Active young female in late teens looking for lasting relationship with OC. Concerned about side effects of acne and bloating.
Career - oriented woman in mid-20s wants to find right OC. Wishes to avoid side effects such as weight gain, headache, and depression. Open to raising a family — but later.

Nonsmoking, healthy woman in late-30s wishes to restart relationship with oral contraceptive. Low metabolic and hormonal impact preferred.

A personalized approach to oral contraceptives.

Because Tri-Norinyl is uniquely phased for all phases of a woman's reproductive life, it's ideal for a wide range of patient types:

Older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic with low-impact norethindrone that *lowers* progestin in late cycle to minimize overall hormonal and metabolic impact.

Career-oriented patients delaying childbearing, because reduced progestin helps minimize side effects that can disrupt daily life, such as weight gain, headache, and depression.

Younger patients just starting contraception, because low-impact norethindrone lowers the risk of acne and bloating, and is increased at mid-cycle, to provide enhanced endometrial support when breakthrough bleeding is most likely to occur.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

Committed to the OB/GYN and women's healthcare

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see next page for brief summary of prescribing information.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (> 8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especiall when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the ini ation or reinstitution of oral contraceptives and at least annually during use of oral co traceptives. These physical examinations should include special reference to bloo pressure, breasts, abdomen and pelvic organs, including cervical cytology and rel vant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vagin bleeding, appropriate diagnostic measures should be conducted to rule out mali nancy. Women with a strong family history of breast cancer or who have breast nodule should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if the elect to use oral contraceptives. Some progestogens may elevate LDL levels and ma render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication shou be discontinued. Steroid hormones may be poorly metabolized in patients wi impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be pr scribed with caution, and only with careful monitoring, in patients with condition which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug disco tinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance shoul be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstru irregularities have been associated with concomitant use of rifampin. A similar asso ation though less marked, has been suggested with barbiturates, phenylbutazon phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected b oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3 increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total th roid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioi munoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circ lating sex steroids and corticoids; however, free or biologically active levels remai unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be clinical significance if a woman becomes pregnant shortly after discontinuing or contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursin mothers and a few adverse effects on the child have been reported, including jaundic and breast enlargement. In addition, oral contraceptives given in the postpartu period may interfere with lactation by decreasing the quantity and quality of brea milk. If possible, the nursing mother should be advised not to use oral contraceptive but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated wit the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arteri thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemo rhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenoma carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use oral contraceptives, although additional confirmatory studies are needed: Mese teric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contr ceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestin symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spo ting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinu tion of treatment • Edema • Melasma which may persist • Breast changes: tenderne enlargement, secretion • Change in weight (increase or decrease) • Change in cervic erosion and secretion • Diminution in lactation when given immediately postpartum Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tol ance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepe ing) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives an the association has been neither confirmed nor refuted: Pre-menstrual syndrome Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosu • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolyt uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses oral contraceptives by young children. Overdosage may cause nausea, and withdraw bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contrace tives are supported by epidemiological studies which largely utilized oral contrace tive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood los and decreased incidence of iron deficiency anemia • Decreased incidence dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovari cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocyst disease of the breast • Decreased incidence of acute pelvic inflammatory disease Decreased incidence of endometrial cancer • Decreased incidence of ovarian canc

Early neonatal mortality and cesarean delivery in Mexico City 22
Jose L. Bobadilla, MD, PhD, and Godfrey J.A. Walker, MD, MFCM
Mexico City, Mexico, and London, England

A study of a representative sample of births in Mexico City is described; the cesarean delivery rate is 27% with an associated increased relative risk of neonatal mortality.

The effect of tetracycline on levels of oral contraceptives 28
Ana A. Murphy, MD, Howard A. Zacur, MD, PhD, Patricia Charache, MD, and Ronald T. Burkman, MD
Baltimore, Maryland

No significant decrease in plasma levels of the oral contraceptive steroids was seen with either "short-term" (24 hours) or "long-term" (5 to 10 days) ingestion of tetracycline.

Venous Doppler ultrasonography in the fetus with nonimmune hydrops 33
Saemundur Gudmundsson, MD, PhD, James C. Huhta, MD, Dennis C. Wood, RDMS, RCPT, Gerald Tulzer, MD, Arnold W. Cohen, MD, and Stuart Weiner, MD
Philadelphia, Pennsylvania

Abnormal Doppler-recorded pulsations in the fetal umbilical vein might be used to distinguish cardiac from noncardiac involvement in nonimmune hydrops and to predict outcome.

The relationships among umbilical artery velocimetry, fetal biophysical profile, and placental inflammation in preterm premature rupture of the membranes 38
Alfred D. Fleming, MD, Carolyn M. Salafia, MD, Anthony M. Vintzileos, MD, John F. Rodis, MD, Winston A. Campbell, MD, and Kimberly F. Bantham, BS
Farmington, Connecticut

In patients with preterm premature rupture of the membranes and placental inflammation, the systolic/diastolic ratio is increased and the biophysical profile is decreased in the last examination within 24 hours of delivery, as compared with previous examinations.

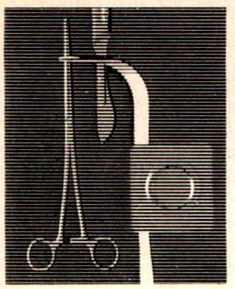
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

Females: 0.9 × value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Human immunodeficiency virus–induced immunosuppression: A risk factor for human papillomavirus infection 42
Roberto Matorras, MD, PhD, Jose M. Ariceta, MD, Angel Rementeria, MD, Jesús Corral, MD, Gloria Gutierrez de Terán, RN, Javier Diez, MD, Francisco Montoya, MD, PhD, and Francisco J. Rodriguez-Escudero, MD, PhD
Bilbao, Spain

Human immunodeficiency virus–positive women were at high risk of human papillomavirus infection, and among them human papillomavirus–associated lesions had a more resistant behavior.

Endometriosis associated with massive ascites and absence of pelvic peritoneum 45
R. Stan Williams, MD, and Rebecca Wagaman, MD
Gainesville, Florida

This article is a case presentation of massive ascites and destruction of the pelvic peritoneum in association with endometriosis.

Endometrial thickness as measured by endovaginal ultrasonography for identifying endometrial abnormality 47
Seth Granberg, MD, Mats Wikland, MD, Bengt Karlsson, MD, Anders Norström, MD, and Lars-Gösta Friberg, MD
Göteborg, Sweden

This article describes the use of endovaginal ultrasonography for detection of endometrial abnormality in women with postmenopausal bleeding.

The use of the Cytobrush cervical sampler in patients with cervical stenosis 52
Mitchel S. Hoffman, MD, Lorraine W. Gordy, CT, and Denis Cavanagh, MD
Tampa, Florida

The use of the Cytobrush cervical sampler for cervical cytologic screening appears to be valuable in patients with cervical stenosis.

Low level of maternal serum α-fetoprotein: Its associated anxiety and the effects of genetic counseling 54
Kathy L. Keenan, MS, Deborah Basso, MD, John Goldkrand, MD, and William J. Butler, MD
Albany, New York

This is a study to quantify parental anxiety after the report of low maternal serum α-fetoprotein results and the extent to which genetic counseling can reduce this anxiety.

Successful antepartum treatment of listeriosis 57
Charles Kalstone, MD
Miami, Florida

Recognizing and treating the pregnant patient with listeriosis can save her fetus.

THE NATURAL CHOICE

GORE-TEX® SOFT TISSUE PATCH

In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

Anemia and spontaneous preterm birth 59
Mark A. Klebanoff, MD, MPH, Patricia H. Shiono, PhD, Joseph V. Selby, MD, MPH, Alan I. Trachtenberg, MD, MPH, and Barry I. Graubard, MA
Bethesda, Maryland, and Oakland, California

Second-trimester anemia was moderately associated with subsequent preterm birth, and third-trimester anemia was not; however, anemia did not explain ethnic differences in preterm birth.

Fetal urine output does not influence residual amniotic fluid volume after premature rupture of membranes 64
William J. Watson, MD, Vern L. Katz, MD, and John W. Seeds, MD
Chapel Hill, North Carolina

Fetal urine output in pregnancies complicated by preterm premature rupture of membranes is similar to that seen in uncomplicated pregnancies with intact membranes.

The diagnosis of ovarian cancer by pathologists: How often do diagnoses by contributing pathologists agree with a panel of gynecologic pathologists? 65
Carl W. Tyler, Jr., MD, Nancy C. Lee, MD, Stanley J. Robboy, MD, Robert J. Kurman, MD, Allen L. Paris, MD, Phyllis A. Wingo, MS, and G. David Williamson, PhD
Atlanta, Georgia, Newark, New Jersey, Baltimore, Maryland, and West Plains, Missouri

In a review of 477 ovarian cancer specimens, three gynecologic pathologists agreed with contributing pathologists on 98%; concurrence on histologic type ranged from 100% to 73%.

Spontaneous ovarian-to-vaginal fistula: A case report 71
Paul Claman, MD, Mark Dover, MD, Raphael Saginur, MD, Hardy Tao, MD, and Manuel Orizaga, MD
Ottawa, Ontario, Canada

A case of spontaneous ovarian-vaginal fistula to a benign ovarian abscess is reported.

Relationship of laparoscopic findings to self-report of pelvic pain 73
Anna L. Stout, PhD, John F. Steege, MD, William C. Dodson, MD, and Claude L. Hughes, MD, PhD
Durham, North Carolina

The degree of pelvic organic pathologic conditions evaluated by diagnostic laparoscopy is not significantly correlated with most self-rated pain levels and functional impairment.

Phosphorus 31 magnetic resonance spectroscopy of human placenta and quantitation with perchloric acid extracts 80
Helen H. Kay, MD, John D. Gordon, MD, Anthony A. Ribeiro, PhD, and Leonard D. Spicer, PhD
Durham, North Carolina

Phosphorus 31 nuclear magnetic resonance spectroscopy of human placental tissue is reported and promises to be an exciting method for placental metabolism studies.

Argon laser versus microscissors for hysteroscopic incision of uterine septa 87
Giovanni Battista Candiani, MD, Paolo Vercellini, MD, Luigi Fedele, MD, Salvatore Garsia, MD, Diana Brioschi, MD, and Laura Villa, MD
Milan, Italy

No significant advantage was offered by argon laser compared with microscissors for hysteroscopic incision of subseptate uterus in 21 women with repeated abortion.

Angiosarcoma of the uterus: A case report 90
Guillermo E. Quinonez, MD, MSc, Maria P. Paraskevas, MD, MSc, Malkit S. Diocee, EMT, and Susan M. Lorimer, MD
Winnipeg, Manitoba, Canada

In this study we report a case of uterine angiosarcoma confirmed by electron microscopy.

Quantitative and qualitative platelet abnormalities during pregnancy 92
Helen Y. How, MD, Frauke Bergmann, MD, Mabel Koshy, MD, Juan Chediak, MD, Celeste Presperin, RN, and Stanley A. Gall, MD
Chicago, Illinois

Transient thrombocytopenia was found in 15 of 4048 pregnant women; in the presence of prolonged bleeding time, an associated functional platelet disorder should be considered.

The clinical implications of subchorionic placental lucencies 99
Vern L. Katz, MD, George F. Blanchard, Jr., BA, RDMS, William J. Watson, MD, Richard C. Miller, MD, Nancy C. Chescheir, MD, and John M. Thorp, Jr., MD
Chapel Hill, North Carolina

Ultrasonographically identified subchorionic placental lucencies are not associated with adverse pregnancy outcome.

The transverse cerebellar diameter in the second trimester is unaffected by Down syndrome 101
Lyndon M. Hill, MD, Dawn Rivello, RDMS, Carol Peterson, RDMS, and Sandra Marchese, MS
Pittsburgh, Pennsylvania

The transverse cerebellar diameter is not altered before 20 weeks' gestation in fetuses with Down syndrome.

Maternal postprandial glucose levels and infant birth weight: The Diabetes in Early Pregnancy Study 103
Lois Jovanovic-Peterson, MD, Charles M. Peterson, MD, George F. Reed, PhD, Boyd E. Metzger, MD, James L. Mills, MD, MS, Robert H. Knopp, MD, Jerome H. Aarons, MD, and the National Institute of Child Health and Human Development—Diabetes in Early Pregnancy Study
Santa Barbara, California, Bethesda, Maryland, Chicago, Illinois, Seattle, Washington, and Pittsburgh, Pennsylvania

Adjusted third-trimester nonfasting glucose levels and glycosylated hemoglobin levels in insulin-dependent diabetic women predict the risk of macrosomia.

Association between hypothermia and mortality rate of premature infants—Revisited 111
Joëlle Hazan, MD, Urs Maag, PhD, and Philippe Chessex, MD
Montreal, Quebec, Canada

The known association between neonatal mortality and hypothermia has no cause-effect relationship in the smallest preterm infants.

The accuracy of clinical findings and laparoscopy in pelvic inflammatory disease 113
John Sellors, MD, James Mahony, PhD, Charles Goldsmith, PhD, Darlyne Rath, BScN, Rajinder Mander, MD, Barry Hunter, MD, Clifford Taylor, MD, David Groves, PhD, Harry Richardson, MD, and Max Chernesky, PhD
Burlington and Hamilton, Ontario, Canada

Clinical, operative, and histopathologic findings suggest that laparoscopy and often endometrial and fimbrial minibiopsy are necessary for the accurate diagnosis of pelvic inflammatory disease.

Antiepileptic medication in pregnancy: Late effects on the children's central nervous system development 121
Michiel C. van der Pol, MD, Mijna Hadders-Algra, MD, Henk J. Huisjes, MD, and Bert C.L. Touwen, MD
Groningen, The Netherlands

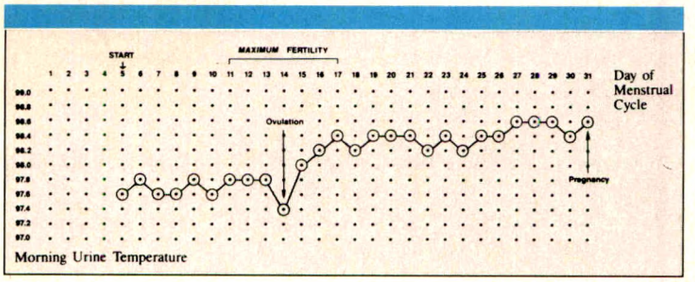
Phenobarbital during pregnancy may lead to microcephaly and impaired cognitive development in offspring but this was not so with carbamazepine; congenital anomalies were related to mother's epilepsy.

Multinuclear spermatozoa associated with polyploidy 128
Firuza R. Parikh, MD, Margaret J. Iannielo, BS, Michael Kashgarian, MD, Alan H. DeCherney, MD, and Gad Lavy, MD
New Haven, Connecticut

The high incidence of polyploidy in human ova as the result of penetration in vitro by multinucleated spermatozoa is reported.

Therapy of persistent human papillomavirus disease with two different interferon species 130
Stanley A. Gall, MD, Lisa Constantine, RN, and Doris Koukol, RN
Louisville, Kentucky

The interferons used in this study were effective in the treatment of persistent human papillomavirus disease of the vulva and enhanced subsequent adjunctive therapies.



Cross-sectional analysis of triplet birth weight 135
J. Stephen Jones, MD, Roger B. Newman, MD, and M. Clinton Miller, PhD
Charleston, South Carolina

Triplet growth appears distinctly linear between 22 and 38 weeks' gestation with mean intratriplet discordance found to be double that of twin pregnancies.

(Contents continued on page 15A)

When it comes to fertility testing, we believe in going strictly by the numbers.

To a woman, ovulation is more than just a physiologic occurrence; it's a vital factor in family planning. Core body temperature rises at ovulation and stays elevated if pregnancy occurs. OvuDate® conveniently and precisely measures core temperature from a first morning urine sample. OvuDate reliably documents a woman's fertility, both when she ovulates and if she's pregnant. [1, 2, 3.]

Not an LH test kit, OvuDate makes home fertility testing simple and accurate. Your patient can now relay important data to you with the precision of numbers instead of colors.

For physician inquiries or additional information, call our toll-free information line **1-800-OVUDATE/1-800-688-3283.** A woman's fertility is too important to leave to guesswork.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: **Robert L. Barbieri, MD**
State University of New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research and serving as a long-term, practical resource.

Subscribe today by returning the attached order form or by calling our toll-free number!

The effects of indomethacin and a β-sympathomimetic agent on the fetal ductus arteriosus during treatment of premature labor: A randomized double-blind study 141
Marianne Eronen, MD, Erkki Pesonen, MD, Tapio Kurki, MD, Olavi Ylikorkala, MD, and Mikko Hallman, MD
Helsinki, Finland

Indomethacin, not nylidrine, given during preterm labor constricts the fetal ductus arteriosus, and this effect increases with gestational age.

A selective serotonin reuptake inhibitor, fluoxetine hydrochloride, modulates the pulsatile release of prolactin in postmenopausal women 147
Randall J. Urban, MD, and Johannes D. Veldhuis, MD
Galveston, Texas, and Charlottesville, Virginia

Short-term activation of the serotoninergic system with an antidepressant drug in the absence of significant estrogen and opiatergic tone increases the secretion of prolactin in postmenopausal women.

Endoscopic sclerotherapy in extrahepatic portal hypertension in pregnancy 152
David Pauzner, MD, Igal Wolman, MD, David Niv, MD, Amos Ber, MD, and Menachem P. David, MD
Tel-Aviv, Israel

Extrahepatic portal hypertension in pregnancy is a rare but potentially hazardous condition; a case report of repeat successful endoscopic treatment in pregnancy is herein presented.

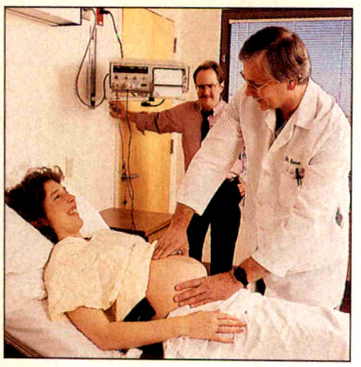
Tables for estimation of individual risks of fetal neural tube and ventral wall defects, incorporating prior probability, maternal serum α-fetoprotein levels, and ultrasonographic examination results 154
James G. Thornton, MD, Richard J. Lilford, PhD, and Robert G. Newcombe, PhD,
Leeds and Cardiff, United Kingdom

Spina bifida risks after screening depend on prior risk, serum α-fetoprotein, and the ultrasonographic sensitivity; tables are provided for estimating individual risks.

Heterotopic pregnancies after in vitro fertilization and embryo transfer 161
Botros Rizk, MD, Seang Lin Tan, MD, Samuel Morcos, MD, Andrew Riddle, MD, Peter Brinsden, MD, Bridgett A. Mason, MB, BS, and Robert G. Edwards, PhD, DSc
London, England

Seventeen heterotopic pregnancies were encountered among 1648 clinical pregnancies during 5 years of in vitro fertilization.

Current Development



A risk-benefit analysis of elective bilateral oophorectomy: Effect of changes in compliance with estrogen therapy on outcome 165
Theodore Speroff, PhD, Neal V. Dawson, MD, Leon Speroff, MD, and Richard J. Haber, MD
Cleveland, Ohio, Portland, Oregon, and San Francisco, California

When compliance with estrogen replacement therapy is considered, life expectancy for perimenopausal women undergoing hysterectomy is maximized by retention of the ovaries rather than by their removal.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Santa Rosa — Opening new hospital featuring seven LDR's. Ten OB/GYN physicians and five nurse practitioners. Specialties include infertility, colposcopy, laser surgery and hysteroscopy. Call required once every nine nights. In Northern California's wine country, one hour north of San Francisco.

Santa Clara/Milpitas/Sunnyvale — 28 member department includes 3 perinatologists, GYN oncologist and reproductive endocrinologist. Ongoing clinical research. Our academic-oriented facility has an independent fully-accredited OB/GYN residency and serves as a core rotation for Stanford Medical Students. Academic appointments possible.

San Jose/Gilroy — Our 18 OB/GYN physicians average 3,000 deliveries per year and offer a full range of services including infertility, dysplasia and gyn-urology. On call approximately three nights per month. In-house Level II nursery; prenatal service shared with our nearby Santa Clara medical center. Satellite office in Gilroy. Located south of San Francisco and about one hour from the Monterey coast. The surrounding hills create a pleasant environment in which to live and work.

Hayward/Fremont — Full range of OB/GYN services with Level III L&D/ICN, 3000 deliveries yearly. Full time staff includes perinatologist and four neonatologists. Medical center and associated medical office located on east shore of San Francisco Bay with easy access to entire Bay Area.

Walnut Creek — Department of 15 physicians, a perinatologist and seven nurse practitioners. Two physicians on call daily. Teaching responsibilities for third year residents affiliated with the University of California at San Francisco. Clinical appointments at UCSF also available. Expansion plans include a large ICN, and within five years, a completely new hospital.

Martinez/Antioch — Southern California climate, Northern California charm, Bay Area location. Primarily in/outpatient GYN, outpatient OB. Seven physicians and four nurse practitioners in office and hospital practice. Deliver at the Walnut Creek Medical Center. High-risk pregnancy clinic at Martinez. Labor room call once or twice a month.

Vallejo/Fairfield/Napa — Seventeen physicians and four nurse practitioners at these facilities. Approximately 2,900 deliveries performed each year at the Vallejo medical center. Usual call is every eighth night. Affiliated with David Grant Medical Center residency program at Travis Air Force Base. Our area offers diverse lifestyle options, with both recreational and cultural attractions nearby.

San Rafael/Petaluma — OB/GYN services are available at both the San Rafael Medical Center and the new Petaluma medical offices which opened in January of 1989.

South Sacramento — Eight physicians and four nurse practitioners serve 104,000 members in fast-growing Central Valley area. Planning new family-oriented L&D facilities.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AJOG-8346, 1814 Franklin, 4th Floor, Oakland, CA 94612. (800) 777-4912. EOE

BASIC SCIENCE SECTION

Characterization of sodium channels in cultured human uterine smooth muscle cells 175

Roger C. Young, MD, PhD, and Lea Herndon-Smith

Charleston, South Carolina

A sodium channel found in cultured human uterine myometrial cells is characterized; whereas the channel was observed under physiologic ion concentrations, it is inactive at physiologic resting membrane potentials.

Cocaine directly augments the α-adrenergic contractile response of the pregnant rabbit uterus 182

William W. Hurd, MD, Patricia A. Robertson, MD, R. Kirk Riemer, PhD, Alan Goldfien, MD, and James M. Roberts, MD

San Francisco, California

Cocaine augments the α-adrenergic contractile response of the pregnant rabbit uterus in vitro by a mechanism that is blocked by the non-β-adrenergic effects of propranolol.

Spontaneous and steroid-induced recurrence of endometriosis after suppression by a gonadotropin-releasing hormone antagonist in the rat 187

Kathy L. Sharpe, PhD, Maria C. Bertero, MD, Kenneth N. Muse, MD, and Michael W. Vernon, PhD

Lexington, Kentucky

The spontaneous recurrence of endometriosis after cessation of gonadotropin-releasing hormone antagonist (antide) therapy is accelerated by selected estrogen and progesterone replacement therapies in the rat.

Diastolic circulatory dynamics in the presence of elevated placental resistance and retrograde diastolic flow in the umbilical artery: A Doppler echographic study in lambs 195

Jean-Claude Fouron, MD, Georges Teyssier, MD, Enrique Maroto, MD, Manon Lessard, RT, and Gerald Marquette, MD

Montreal, Quebec, Canada

Diastolic reverse flow in the umbilical artery of lambs reflects an altered fetal hemodynamic state in which the lowest vascular resistance is no longer at the placental level.

Forskolin and methotrexate induce an intermediate trophoblast phenotype in cultured human choriocarcinoma cells 204

Robert N. Taylor, MD, PhD, Erin D. Newman, and Shiuan Chen, PhD

San Francisco and Duarte, California

Human choriocarcinoma cells with cytotrophoblastic characteristics were induced to differentiate into intermediate trophoblast-like cells after exposure to forskolin and methotrexate in vitro.

Contents continued from page 17A

Factors influencing the initiation of nonshivering thermogenesis 210
Tania R. Gunn, Karen T. Ball, MSc, Gordon G. Power, MD, and Peter D. Gluckman
Auckland, New Zealand, and Loma Linda, California

Cutaneous cooling, oxygenation, and umbilical cord occlusion are major factors initiating nonshivering thermogenesis at birth.

Current Development

Transplantation of fetal cells 218
Timothy M. Crombleholme, MD, Jacob C. Langer, MD, Michael R. Harrison, MD, and Esmail D. Zanjani, PhD
San Francisco, California, and Reno, Nevada

Cellular transplantation is an attractive alternative to whole-organ transplantation, and the use of fetal cells may improve engraftment and avoid graft-versus-host disease.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Calcium every day
Aerobics every wee
Bone loss every yea

P 24, 301

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®
(conjugated estrogens tablets)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

The appearance of these tablets is a trademark of Wyeth-Ayerst Laboratories.

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

SPECIAL PREVIEW

A New Osteoporosis Patient Information Program

One out of four women over 50 will get osteoporosis.

To help avoid being one of them, call 1 800 444-4549.

After 50, a woman begins losing her natural defense against osteoporosis...estrogen.

Estrogen, together with calcium, can play an important role in keeping your bones strong. As you reach menopause, your estrogen levels begin to drop, and you become increasingly at risk of developing weakened bones and potentially crippling fractures.

Taking low dose **PREMARIN®** (conjugated estrogens tablets) is the single most effective way to prevent osteoporosis after menopause.

Premarin® is estrogen obtained exclusively from natural sources, and has been used and trusted by women and physicians for nearly 50 years.

See the following page for more information.

Call today for free information.

We'll send you a brochure that tells you what you should know about estrogen, menopause, and osteoporosis. Then, we strongly suggest you visit your doctor, since taking any drug may involve some chance of side effects, and only a doctor can tell you whether Premarin is right for you. In fact, we'll even send you a certificate you can redeem for a free exercise videotape after you make that important visit. Just call the toll-free number above or write: Premarin Osteoporosis Information Center, Box 5201, Miami, FL 33102

WYETH-AYERST LABORATORIES | WORLDWIDE LEADERSHIP IN FEMALE HEALTH-CARE

This message will soon be appearing in consumer magazines. It announces a new program designed to inform postmenopausal women about osteoporosis and PREMARIN® (conjugated estrogens tablets)...and to urge them to visit their doctors for more information.

We wanted you to be the first to know...so we can work together to prevent this devastating disease.

Please see brief summary of prescribing information on adjacent page.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi and from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than U.S. in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent is included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH, BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thrombo-embolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners pre-scribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, con-firming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic mea-sures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

EDITORIAL

A change in the masthead

Many of you may have noticed significant changes on the cover of this issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. John Brewer, after 32 years of dedicated service to the JOURNAL as Editor in Chief, has requested that he become Editor Emeritus. We, and the Publisher, tried to convince John to postpone this decision for a few years, but anyone who knows John realizes that after he has thought through a difficult decision, it is almost impossible to get him to change his mind. We have prospered from and enjoyed tremendously our 20-year association with John as our JOURNAL boss and mentor role model. He has been a personal friend who has given us tips on everything from life to golf, each one given with a deep background of experience and expertise, and always with our best interests in mind. John has also been a personal friend to each of you who reads the JOURNAL by insisting on the most rigorous standards for the authors, the Editors, and the Publisher: every *i* dotted and every *t* crossed, all for the benefit of the reader. He has simultaneously embraced change when he felt it would make the JOURNAL stronger: peer review of all articles, development of the Clinical Opinion section, and addition of the short abstract with the title in the table of contents to name just a few. If you think this guiding hand will be completely lost, rest assured it will not. John has agreed to attend our editorial meetings and for this we, the Editors and Publisher, know the reading public will be grateful.

You will also notice some new names on the cover. Drs. Gabbe, Garite, Kim, and Manetta have agreed to become Associate Editors of the JOURNAL. We were very pleased that such outstanding people in the specialty with special expertise in maternal-fetal medicine, endocrinology-infertility, and gynecologic oncology would join us. They add further depth to the JOURNAL staff, which should assure both reader and author that we are constantly trying to improve the JOURNAL. Having our Associate Editors in our own institutions should speed the flow of articles and allow us to delete one JOURNAL office. This reorganization is not accomplished without loss. Dr. Gerbie, who has been an important part of the JOURNAL as an Associate Editor in Dr. Brewer's office, will no longer serve in that capacity. We thank him for all his contributions in the past and know that we can call on him for advice in the future. Sandra Fernandez, Senior Editorial Assistant for the JOURNAL, will be assuming new duties at Northwestern University School of Medicine. Her efficient office management and her expertise in working with authors, reviewers, and Mosby–Year Book personnel have contributed immensely to the success of the JOURNAL. Fortunately for us she has agreed to help if the need arises. Her vast knowledge about the workings of the JOURNAL ensures that we will be consulting her in the future.

Change is inevitable. It is always accompanied by regrets at the good that is lost; however, it can make us work harder to live up to the standards John Brewer has set for the JOURNAL. The Editors and Associate Editors assure you that this will be our goal.

The Editors

Clinical Opinion

Blood pressure self-monitoring during pregnancy: Practical considerations

Frederick P. Zuspan, MD,[a] and William F. Rayburn, MD[b]
Columbus, Ohio, and Omaha, Nebraska

Portable electronic and mechanical aneroid instruments for blood pressure self-monitoring are available, inexpensive, and reasonably accurate. Instructing the patient at risk for borderline, mild hypertension or chronic hypertension during pregnancy on self-monitoring of blood pressure has advantages. Combined with conventional office measurements, many daily recordings give an accurate picture of an individual's dynamic blood pressure. Lower blood pressures commonly found outside the office are likely attributable to an increased awareness, less anxiety, and attention by the patient to nonpharmacologic factors. Such persons may well avoid antihypertensive therapy or antepartum hospitalization. This information provides a strong incentive to undertake and adhere to an appropriate plan of treatment for those patients whose hypertension is confirmed by blood pressure self-monitoring technique. We consider blood pressure self-measurement to complement other reported monitoring techniques for active patient participation at home or in the work setting. It also permits an early evaluation of blood pressure alterations to rule out preeclampsia, especially in the pregnant patient with chronic essential hypertension. (AM J OBSTET GYNECOL 1991;164:2-6.)

Key words: Blood pressure self-monitoring, pregnancy, hypertension, preeclampsia

Most health care personnel tend to think of hypertension during pregnancy as a fixed entity, but blood pressures actually show daily variations regardless of physical and mental activities. "White coat" hypertension is a specific phenomenon—possibly a conditioned response—that does not necessarily indicate excessive blood pressure reactivity at other times.[1] Thus even confirming the diagnosis of hypertension during pregnancy by verifying high blood pressure values during repeated office visits is usually inadequate. Blood pressure self-determinations will often answer these questions.

Blood pressure self-monitoring has been proposed for the evaluation and treatment of pregnant patients at risk for or presumed to have borderline, mild, or overt hypertension.[2] Recordings of blood pressure over the day and night are "dynamic" rather than "static" and, combined with conventional office measurements, may provide the degree of accuracy necessary to plan management. This manuscript will discuss our clinical opinions about the impact of blood pressure self-monitoring on decision-making for management and eventual perinatal outcomes. We will also describe the equipment and procedures and identify patients who would benefit most from such monitoring.

Concept of blood pressure self-monitoring

Studies of whole-day blood pressure monitoring have used portable intraarterial direct surveillance systems in nonpregnant adults.[3, 4] Although this approach provides accurate and continuous measurements, its invasive and costly nature makes it impractical for routine clinical applications. The use of blood pressure self-monitoring devices is more practical. Recordings at home, work, or elsewhere allow patients and their families to actively participate in the treatment program. Those patients receiving antihypertensive therapy are provided an instant visual evidence of blood pressure change and their response to therapy. This instant feedback of information should enhance compliance with the prescribed treatment programs.

Measurements outside the obstetrician's office may aid in making treatment decisions for pregnant patients with hypertension and in evaluating or adjusting ther-

apy.[2] Blood pressure self-measurements may be particularly useful for patients on a treatment program that includes nonpharmacologic measures. It may also lead to simplification of antihypertensive treatment, possibly resulting in a reduction of drug doses, fewer side effects, and increased compliance. Once the "goal" blood pressure is achieved, maintained, and understood by the patient, the self-recordings may permit longer intervals between office visits. We normally would like to examine pregnant patients with mild chronic hypertension (diastolic pressure >90 mm Hg) at least every 2 weeks until the thirtieth week of gestation and then on a weekly basis.

Investigations during pregnancy

For more than 12 years, we have encouraged our pregnant patients to measure their own blood pressures and have found the practice satisfactory in monitoring those with hypertension from any cause. Blood pressure values obtained at home have been lower than clinic measures in 52% of the cases. Averaged home measures have been equivalent (within 5 mm Hg) to clinic measures in only 28% of clinic visits.[2] Pressures persistently higher at home than in the clinic have been extremely rare. These facts should cause concern in evaluating data in publications that do not utilize blood pressure self-monitoring because many patients who probably do not need it will be placed on a regimen of antihypertensive medication. These observations have been confirmed with a telemetric technique to transmit blood pressures from home to clinic.[5] Self-recordings of blood pressure have improved the patient's awareness and provide additional information with which to formulate management decisions. Lower blood pressures at home are expected to be associated with bed rest, positional change, and the averaging of daily recordings, rather than the customary one or two values obtained during weekly or biweekly office visits.

We feel that pregnant women with hypertension may be managed at home if blood pressures are borderline or mildly elevated in the clinic but normal at home. An investigation conducted at our clinics during a 2-year period involved pregnant women who had hypertension before being seen initially in the first or early second trimester.[6] Once they had learned blood pressure self-monitoring, half of the women who had taken medications (usually diuretics) before pregnancy were able to discontinue these medications because of consistently normal blood pressure values outside the clinic. Conversely, methyldopa (Aldomet) alone or in combination with hydralazine or a β-blocking drug was started in those patients whose blood pressures were elevated both at home and in the clinic.

Performing a large randomized study to test the value of blood pressure self-monitoring during pregnancy is extremely difficult because of ethical considerations and the limited number of study cases. We have used for comparison a historical control group of chronically hypertensive women monitored only at clinic visits.[6] The same written protocols were followed for both control and self-monitoring groups. The control group showed a twofold increase in the number of patients for whom antihypertensive medications were prescribed by the end of pregnancy, in contrast to a slight decrease in the number needing medication in the self-monitoring group.

Our findings support those by others that antihypertensive medications for women with mild chronic hypertension are useful in diminishing maternal complications but not necessarily improving perinatal outcomes.[6] When elevated blood pressures persist at home, the patient's concerns are warranted, and we have recommended a reduction of activity, beginning or altering drug therapy, or admission to the hospital for closer observation. We continue to support the concept that chronically hypertensive women may be managed at home if blood pressures are borderline or mildly elevated in the clinic but normal at home. Nonpharmacologic actions (mainly increased bed rest) may contribute to feelings of well-being, which in turn lower blood pressure levels.

Blood pressure self-monitoring should lower the cost of obstetric prenatal care. The medical supplies needed are a blood pressure kit and printed recording sheet. Fewer antenatal hospitalizations and more precise drug prescribing of fewer drugs have been documented. We previously found that antepartum hospitalization for hypertension-related concerns was more than twice as common for mothers whose blood pressures were monitored only in the clinic or office than for those with follow-up both at home and in the office.[6]

Blood pressure devices

Portable electronic and mechanical aneroid devices suitable for home use may be purchased at most retail department and pharmacy stores, and their reliability has been described.[7] Approximately one third of these kits are simple mechanical devices that require reading a pressure gauge. These are called mechanical aneroid ("without liquid") models to distinguish them from those using a column of mercury. Most mechanical monitors are designed for one-handed use. Many have a stethoscope bell attached to the cuff for easy positioning over the brachial artery. With some, the patient must wedge the bell under the cuff, and most cuffs are marked to help position the bell correctly.

The remaining models are battery-operated portable electronic units that display pressures digitally. These oscillometric devices sense blood flow sounds as the cuff is deflated automatically. Cuffs on less expensive models are semiautomatic and must be pumped manually. Proper cuff placement is important. These units are

more sensitive to arm movements and may give a false reading or "error" message unless the patient remains still.

The electronic devices are virtually foolproof. We have found them to be easier for our pregnant patients to use than mechanical aneroid types.[8, 9] They do not require a stethoscope, and the digital displays are easy to read. All the cuffs close with Velcro fasteners, and most are easy to place on one's own arm. Each instrument has an air pump with a slow deflation rate (2 mm/sec) to improve sensitivity. Because of their greater complexity and sensitivity, they are more likely to become inaccurate and should be recalibrated at the doctor's office at least once yearly. One advantage is patient ease in recordings when in the lateral recumbent position.

We have found standard cuffs to fit most pregnant adults, but women with large upper arms (≥35 cm circumference) may have trouble.[10] Using a standard cuff (12 × 23 cm) that is too small may cause falsely elevated blood pressure readings. Larger cuffs (15 × 33 cm), available from medical supply houses, can be used with any mechanical aneroid model. Electronic models may require cuffs with special sensors, not always available in larger sizes.

Ratings in a *Consumer Reports* publication[7] showed that, as a group, the mechanical aneroid models were more accurate than the more complex electronic models. This finding may be explained by the electronic circuitry, which could not sense arterial signals quite as well as a person listening carefully with a stethoscope. Although they were found to be off by up to 5 to 7 mm Hg, the electronic units were rated as good enough for tracking long-term progress.[7-9]

With prices ranging from $18 to $30, many of the top-rated mechanical aneroid models would be good choices, depending on their features. They do require dexterity, good hearing, good eyesight, and some training and practice. We prefer that patients purchase the electronic models for ease of application and for minimizing interobserver bias.[8] The most compact electronic brands (Marshall, Pollenex, Norelco, Sunbeam) cost less than $40 and appear to be as accurate as others priced up to $100.[9]

Patient selection and instruction

Blood pressure self-monitoring is indicated for all pregnant patients with blood pressure of 140/90 mm Hg as measured in the clinic. This includes patients with chronic hypertension or elevated blood pressure first noted during the current pregnancy. Persistently elevated blood pressure places the patient at risk for needing antihypertensive medication, requiring preterm delivery, and having unfavorable perinatal outcome.

We think that with proper instruction and sufficient practice, patients or family members can become confident and aware of conditions related to changes in measured blood pressure. Our patients are taught how to measure and record blood pressure by a well-trained nurse. A dual-headed stethoscope teaches the patient the Korotkoff I, IV, and V sounds. The ones most accurate for pregnancy are Korotkoff I and IV since pregnancy is a high-cardiac-output condition.[11] The problem of whether to use the Korotkoff IV or V sound can be handled by recording all three (i.e., 140/90/86). We keep several blood pressure kits in our clinic for instruction and use by patients.

We have found that cuffs vary in ease of application; particularly simple are those with a slide bar on a mechanical aneroid unit.[8] Placement of the cuff and stethoscope (if necessary) by the patient should be observed closely. The cuff is to be positioned on the same arm each time at the level of the heart, with the sensor placed over the brachial artery.[12] The cuff is then insufflated to a value between 150 and 170 mm Hg. We prefer the left arm.

A stethoscope with two sets of ear pieces, one for the patient and one for the nurse, assures that the patient is reading the blood pressure correctly on a mechanical aneroid unit. The patient then records the blood pressure in a similar fashion each time. Diastolic pressures measured at Korotkoff IV sound correspond better to the intraarterial diastolic pressure. During pregnancy the difference between diastolic recordings at Korotkoff IV and V sounds can be remarkable, and sometimes Korotkoff V sound is 0.[13] The explanation is that the pregnant woman has a hyperkinetic circulation. It is recommended that all three sounds be recorded (i.e., I, IV, and V) to avoid confusion when others examine the patient.

Blood pressure is measured most easily with the patient in a sitting position. Readings using only the right arm as the patient reclines in a left lateral recumbent position may be inaccurate during pregnancy, since any measured decrease in blood pressure does not necessarily represent a fall in real blood pressure as measured in the ascending aorta.[14] We have demonstrated that blood pressures measured in the lateral recumbent position throughout pregnancy can be comparable; that is, the twelfth week of gestation can be compared to the twenty-fourth and thirty-sixth weeks since the enlarging uterus does not effect cardiovascular changes in the lateral position. There have been no prospective studies done that used both sitting and lateral recumbent positions in pregnancy.

Blood pressures have been reported to be lowest in the morning and highest in the afternoon, highest sitting or standing and lowest in the lateral recumbent position; hence patients are instructed to take their

daily measurements in the morning before rising and in the afternoon before resting. When position is taken into account, any decrease in blood pressure during the night in any individual is actually substantially smaller than the measurement suggests.[15]

The measurement of blood pressure by our patients and office staff requires the same methodologic rigor as other medical procedures. Failure to carry out these procedures markedly reduces their value in prenatal care and clinical research projects. It has been identified that a trained observer can reproduce blood pressure measurements ± 4 mm Hg, whereas "clinic values" may vary by 10 mm Hg. It is also interesting that "clinic values" showed more than 50% of readings ending in zero, whereas the trained observer showed only 14% ending in zero. Measurement devices must be standardized and regularly maintained.[11]

Patients are given a form on which to report their readings. These reports are placed on the prenatal chart at each office visit. Additionally, patients are asked to record any situation that may explain fluctuations in the blood pressure, such as unusual activities or interpersonal interactions or any occasion on which medications were not taken.

Criticisms and future needs

Limitations with self-administered blood pressure measurement must be considered along with benefits. The primary concern is inadequate training in measurement technique, leading to inaccurate measurement and misinterpretation of the measurements.[11] In-service training of all personnel utilizing a two-headed stethoscope will go a long way toward correcting errors and casualness of the readings. Normotensive values are reassuring, while elevated readings obtained through self-measurement are only an indication that further evaluation is needed. The diagnosis of hypertension can be made only by a physician who interprets the significance of the blood pressure readings along with other data relevant to the individual patient.

Blood pressure self-measurement may be more suitable for some patients than others. Although the situation is uncommon, some persons may become overly conscious of blood pressure and alarmed at fluctuations associated with daily living. Misinterpretation or overreaction to one or more measurements may cause distress without proper medical consultation. A careful education program on the use of the device and the meaning of the results is necessary. We have seen no deleterious effects on patients because of increased knowledge of daily blood pressure values. Many have said it allayed their apprehension to know the readings and to be part of the health care team.

Accuracy of the two types of devices (mechanical aneroid and electronic) has been tested in pregnant patients; both types provide a reasonable means of providing blood pressure self-measurement.[8, 9] We recommend that any device be compared with a standard mercury sphygmomanometer found in the clinic. The random-zero mercury sphygmomanometer, when used properly, is still the standard against which all other blood pressure measurement devices are compared.[3, 11] The greatest emphasis should be placed on the precision of the diastolic reading. Diastolic pressure changes as small as 5 mm Hg can shift the diagnosis from mild to moderate hypertension or from mild hypertension to normal.[1] The variation of taking the blood pressure may vary by 10 mm Hg. Nearly every monitor has given averaged readings quite close to the nurse's—typically within 4 mm Hg or less. As mentioned previously, measurements with a cuff that is too small may result in falsely elevated readings in an obese person.

Regardless of the type of equipment, patients benefit from written instructions on how to measure blood pressure. The manufacturer's printed instructions accompanying the devices usually specify that the arm be supported and bared and that an appropriate-sized cuff be used. The obstetrician who recommends self-measurement should provide or arrange for patient instruction in measurement, initial and periodic calibration, and record-keeping techniques.

Users of any device should also be provided with information about where to obtain follow-up information after a series of elevated readings. We counsel our patients to be aware that readings less than 140/90 mm Hg are considered normal, although a diastolic pressure of 85 to 89 mm Hg during pregnancy warrants further observation. A single elevated reading does not constitute a diagnosis of hypertension but is only a value. The patient should be instructed to contact the office promptly if readings remain elevated. Pregnant women known to have hypertension should continue their drug therapy and report blood pressure to the obstetrician at regularly scheduled visits.

Noninvasive ambulatory blood pressure monitoring devices have become available for the purpose of more carefully evaluating adults with preliminary clinical diagnosis of mild to moderate hypertension.[4] These electronic digital monitors record blood pressures continuously for 24-hour periods. Averaged readings are more informative to the physician and are thought to be more predictive of target organ involvement and cardiovascular complications than casual monitoring in the clinic.[4] Although its use in pregnancy has not yet been described, this means of monitoring may permit repeated measurement and recording of blood pressures over protracted time periods as subjects continue routine activities. However, high cost and questionable long-term accuracy substantially limit its routine clinical use.[3]

More prospective studies during pregnancy are needed to confirm our observations about the benefits of blood pressure self-monitoring, as well as the position in which the blood pressure should be taken (i.e., sitting or lateral recumbent). Clinical research during pregnancy using both office and home blood pressure determinations should also be more appropriate for evaluating the efficacy of antihypertensive therapy. Blood pressure self-monitoring should permit safer management of the majority of study pregnancies outside the hospital or earlier hospitalization before the next office visit if conditions worsen. We often encourage patients to check urine for protein by dipstick at home.

We consider blood pressure self-measurements to be complementary to monitoring techniques such as maternal capillary blood glucose determinations and uterine activity monitoring for active patient participation at home. A more sophisticated technique of measuring maternal blood pressure in the home with an automatic microcomputer-assisted instrument (Dinamap, Applied Medical Research Corporation, Tampa) with telemetric transfer of information to the clinic may be appealing in certain pregnant women with hypertension.[5] Such indirect determinations of blood pressure have been evaluated during pregnancy and found to eliminate the problem of interobservor error which otherwise becomes evident when blood pressure is checked antenatally.[16] This concept also requires further investigation, since it offers promise not only of reducing the cost of prenatal care but also of improving the pregnant woman's acceptance of the need for hospitalization for hypertension. This may be one method of picking up episodic hypertension during the day so that appropriate therapy or workup can be done.

Dissection of the cardinal ligament in radical hysterectomy for cervical cancer with emphasis on the lateral ligament

Yoshihiko Yabuki, MD, Akihiro Asamoto, MD, Tsutomu Hoshiba, MD, Hideaki Nishimoto, MD, and Shuichi Kitamura, MD

Kanazawa, Japan

Surgical experience with carcinomas of the uterus and rectum has provided new insights into the surgical anatomy of a lamina, which separates the paravesical space from the pararectal space. It has been proved that each of the lamina consists of the cardinal and lateral ligaments and pelvic splanchnic nerves, descending in the following order. The cardinal and lateral ligaments, as a connective stalk, insert into the lateral walls of the uterus and rectum extending from the inner aspect of the pelvic wall. Clarification of this structural relationship led to the development of a new procedure for the dissection of the cardinal ligament in radical hysterectomy, while still preserving the lateral ligament. This facilitated systematic dissection of the cardinal and uterosacral ligaments with posterior manipulation, leading to a reduction in blood loss and to prevention of brisk bleeding from the venous plexuses. (AM J OBSTET GYNECOL 1991;164:7-14.)

Key words: Cardinal ligament; lateral ligament; radical hysterectomy; cervical cancer; ultrasonic surgical aspirator

Dissection of the cardinal ligament is one of the most critical procedures in radical hysterectomy, requiring skills of the highest degree. Over the years this procedure has been greatly influenced by individual surgeons and the differences in their techniques. The 5-year survival rate of patients who have surgical treatment for uterine cancer has already peaked[1] and to improve it there must be a narrowing of these differences and safer techniques. Today's dissection of the cardinal ligament owes much to the groundwork of Latzko (1919),[2] Okabayashi (1921),[3] and Meigs (1944)[4] who improved the original Wertheim operation.[5] They had a common factor in their surgical procedure, which was to expose the paravesical and pararectal spaces and then separate the retinaculum uteri into pars anterior, medial, and posterior, followed by resection of each pars individually. This made systematic and extensive resection of the parametrial ligament possible.

With regard to the cardinal ligament dissection, Meigs[6] improved the Wertheim operation in a comparatively orthodox manner by mere dissection of the Mackenrodt ligament, whereas Latzko[7] and Okabayashi[3, 8] pursued a radical approach by resection of the ligament, lateral stalk of the pelvis, deep down in the pelvic floor. This procedural difference made definition of the cardinal ligament unclear. Specifically, the anatomy and operative manipulation of the inferior border of the cardinal ligament was not always clearly defined. An operation performed with the boundaries of the base of the ligament and its adjacent organs undefined is in danger of damaging blood vessels and nerves by invasion into adjacent tissues. Especially, unskilled technique may cause an unexpected massive hemorrhage.

Kobayashi[9, 10] improved the Latzko and Okabayashi operation by separating the cardinal ligament into the pars nervosa and pars vasculosa after opening the paravesical and pararectal spaces completely to the superior surface of the levator ani so that the vesicular function was preserved by leaving the pars nervosa behind. This manipulation made more detailed explanation of the anatomy of the cardinal ligament very clear, but it was not stated why a part of it remained in the pelvirectal space.

With a view to further understanding the relationship between the parametrium and paraproctium, we performed operations for advanced rectal cancer and came to the following conclusions[11, 12]: (1) Metastasis of the cardinal lymph nodes found in many advanced rectal cancers suggested some continuity between the parametrium and paraproctium, and (2) After an anterior resection of the rectum together with a radical hysterectomy, a view of the dissected end of the ligament on the inner aspect of the pelvic wall is the same as that by radical hysterectomy with a simultaneous resection of the pars vasculosa and pars nervosa (i.e., the Oka-

bayashi operation). This finding coincides with that of a deep pelvic dissection with total pelvic exenteration reported by Mattingly.[13]

Furthermore, when dissecting the cardinal ligament, the visceral branch of the internal iliac vessels (i.e., the deep uterine vein and middle rectal vessels) are exposed at their bifurcation and followed up to the runnings. The results led us to make the following inferences[12]: (1) In conventional radical hysterectomy,[3, 7, 9, 14, 15] the Mackenrodt ligament and lateral ligament,[16] which connects the rectum to the posterolateral pelvic wall, in which the middle rectal vessels pass at the level of the third sacral vertebra, have not been clearly differentiated, and (2) So-called cardinal ligament excised in many conventional radical hysterectomies may be a combined connective stalk consisting of the Mackenrodt and lateral ligaments and sometimes even the pelvic splanchnic nerves.

These inferences are necessary to clarify the anatomic relationship among the cardinal and lateral ligaments and pelvic splanchnic nerves. To our knowledge, no textbook of gynecosurgical procedures or anatomy is available that describes these two ligaments in a mutually related manner. Only the concept of Gefäß-Nerven-Leitplatte des Beckens as described by E. Pernkopf[17] (connective stalk, coated with visceral pelvic fascia, connects the lateral pelvic wall and the organs of the lesser pelvis) gives any suggestions similar to our opinions about the cardinal ligament.

In this article we describe our method of dissecting the cardinal ligament on the basis of the knowledge and findings of the surgical anatomy of the cardinal and lateral ligaments derived from operations for rectal cancer. It is hoped that our hypotheses will stimulate discussions among the readership on this matter and further verifications will be pursued.

Method

Subjects consisted of 41 patients with uterine cancer and 10 patients with rectal cancer on which we performed radical hysterectomy. In accordance with the Okabayashi-Meigs method, radical hysterectomy for uterine or rectal cancer was carried out by the following procedure: abdominal incision, severance of the round

and pelvic infundibular ligaments, open the peritonium to the iliac fossa, exposure of the paravesical and pararectal spaces, dissection of the intrapelvic lymph nodes, manipulation of the opposite side, separation and severance of the uterine artery, isolation of the ureter, separation and severance of the cardinal ligament, manipulation of the opposite side, separation of the rectum from the uterus, severance of the uterosacral and rectovaginal ligaments, manipulation of the opposite side, separation of the bladder, separation and severance of the superficial and deep layers of the vesicouterine ligament, resection of the paravaginal connective tissue, manipulation of the opposite side, transection of the vagina, and closure.

Separation and removal of the cadinal ligament and lymphatic tissues were carried out in part with an ultrasonic surgical aspirator (Cavitron Surgical Systems Inc., Stamford, Conn.). The operative condition of the ultrasonic surgical aspirator was as follows: an ultrasound frequency of 150 to 210 μm with a suction pressure of 200 to 400 mm Hg and an irrigation rate of 30 to 40 cc per minute. The Student t test was used to determine whether there was a significant difference in blood loss between patients who underwent radical hysterectomy before 1985 and those after 1987. The level of significance was set at 0.05 α-level. With consideration of the Japanese physique, we used the modified Broca index of weight/(height − 100) × 0.9 to express the degree of obesity.

Results

Surgicoanatomic relationship between the cardinal and lateral ligaments. Fig. 1 shows the specimen tissue for rectal cancer and its pelvic severed end. The operation was carried out by rectal transection and radical hysterectomy. Intraoperative observation and postoperative angiography of the surgical specimen showed that the vessels on the photomicrograph of the dissected ligament (Fig. 2) are in the following descending order: uterine artery, deep uterine vein, and middle rectal artery and vein. These findings indicate that the cardinal and lateral ligaments and pelvic splanchnic nerves form a lamina, as schematically shown in Fig. 3, which connects the uterus and rectum with the lateral inner aspect of the pelvic wall. The space caudal to the lamina is the paravesical space (actually the paravesical fossa and caudal part of the pararectal fossa), whereas the one that is on the cranial side is the pararectal space (actually the cranial part of the pararectal fossa).

All major blood vessels in the lamina are visceral branches of the internal iliac vessel in which the uterine artery and the superficial and deep uterine veins pass through the cardinal ligament, whereas the middle rectal artery and vein pass through the lateral ligament. As shown in Fig. 4, the deep uterine vein passes through the cardinal ligament at the level of the ischial

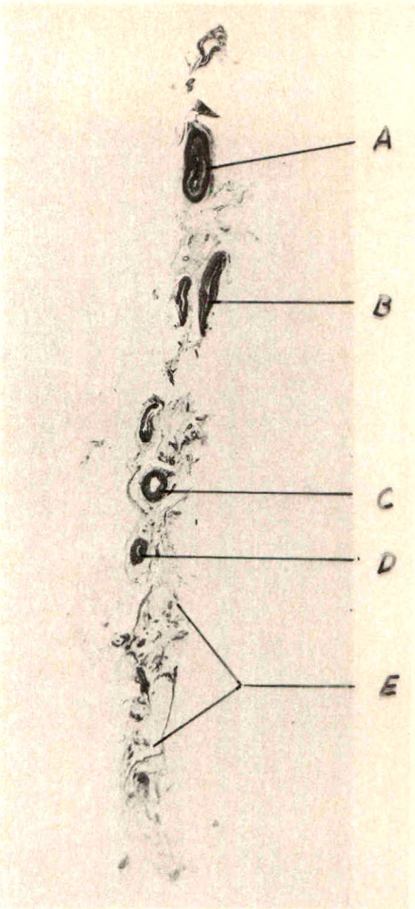

Fig. 2. Photomicrograph of resected laminae. (Elastica van Gieson stain; ×1.) *A*, Uterine artery; *B*, deep uterine vein; *C*, middle rectal artery; *D*, middle rectal vein; and *E*, pelvic splanchnic nerves.

spine and joins the internal iliac vein. The middle rectal artery branches mainly from the common trunk of the inferior gluteal and internal pudendal arteries and travels inferiorly along the deep uterine vein to the side of the rectum. The middle rectal vein passes through a similar course with a number of aberrations.

Dissection of the cardinal ligament. When the operation has proceeded as far as isolation of the ureter, the lamina becomes visible resembling a bridge spanning the paravesical and pararectal spaces. The dissection of the cardinal ligament commences with a resection of the strong fibrous tissue, that is, fascia pelvis visceralis as described by E. Pernkopf,[17] constituting the anterior and posterior surfaces of the lamina. This fibrous tissue is separated and severed accordingly. After removal of the fascia, the intraligamental lymph nodes and fibrous and fatty areolar tissues are removed with a pair of hookless dissecting forceps and an ultrasonic surgical aspirator or a surgical suction apparatus at a pressure of approximately 200 mm Hg, thereby re-

vealing the deep uterine vein and the lateral ligament containing the middle rectal vessel and neural part below it (Fig. 5).

The exposed deep uterine vein and lateral ligament are separated from each other by insertion of Kelly's forceps. The former is ligated and severed on the pelvic side of the vessel's bifurcation (Fig. 6). The uterine side of the severed end of the deep uterine vein is raised,

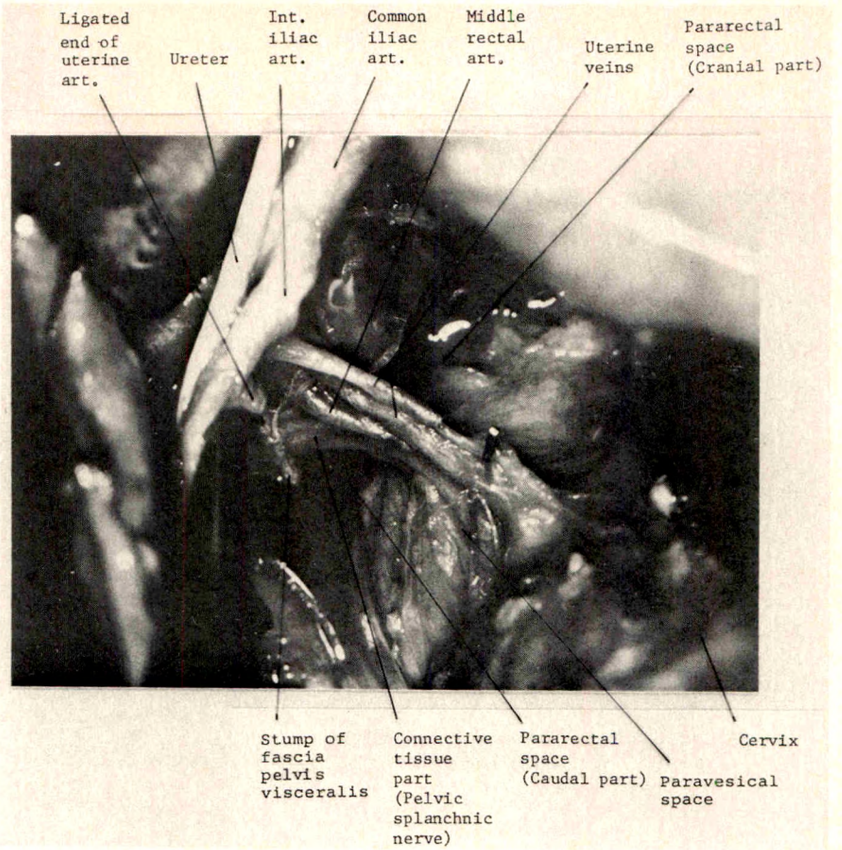

Fig. 5. Excision of fascia covering ligaments after developing paravesical space and pararectal space exposes vascular part and part of connective tissue. According to standard method for cardinal ligament dissection as used in Japan, ligaments are cut through a tunnel constructed between pars vasculosa and pars nervosa or beneath pars nervosa.

separating its distal segment from the lateral ligament up to the uterine cervix. In this way, both the cardinal and lateral ligaments are separated in their entirety and the rectovaginal ligament appears at the separated end (*arrow*, Fig. 4). At this time, care must be taken of hemorrhaging as a result of invasion into the rectouterine venous plexus. Finally, tissues surrounding the lateral ligament are adequately removed by the use of a ultrasonic surgical aspirator, completing the dissection of the cardinal ligament.

The tissue specimen (Fig. 7) removed by the conventional method is compared with that removed by the lateral ligament saving method. In the latter case the pelvic splanchnic nerves remain intact.

Benefits of the new surgical procedure. The amount of blood loss was measured at 30-minute intervals in 20 patients who underwent standard radical hysterectomy before 1985, at which time we realized the presence of the lateral ligament. Two years after the establishment of our new operative measure from 1987 through 1988 we did a comparison of blood loss on 21 patients with that of the prior group of 20 patients (Fig. 8). Table I shows operative information on patients of both groups. The time course of the operative procedure was judged from the anesthetic record, the intraoperative photographing time, and our operative speed experience. Blood loss during cardinal ligament dissection was significantly reduced in the latter group for the following reasons: (1) clarification of laminae anatomy by means of ultrasonic surgical aspirators; (2) avoidance of complete exposure of the pararectal space by disclosure of the superior surface of the levator ani only as required in the standard radical hysterectomy; and (3) systematization of posterior manipulations such as dissection of the uterosacral ligament (Fig. 9) because of the preservation of the lateral ligament. These improvements led to the prevention of intraligamental rupture of vessels and breakage of the venous plexuses

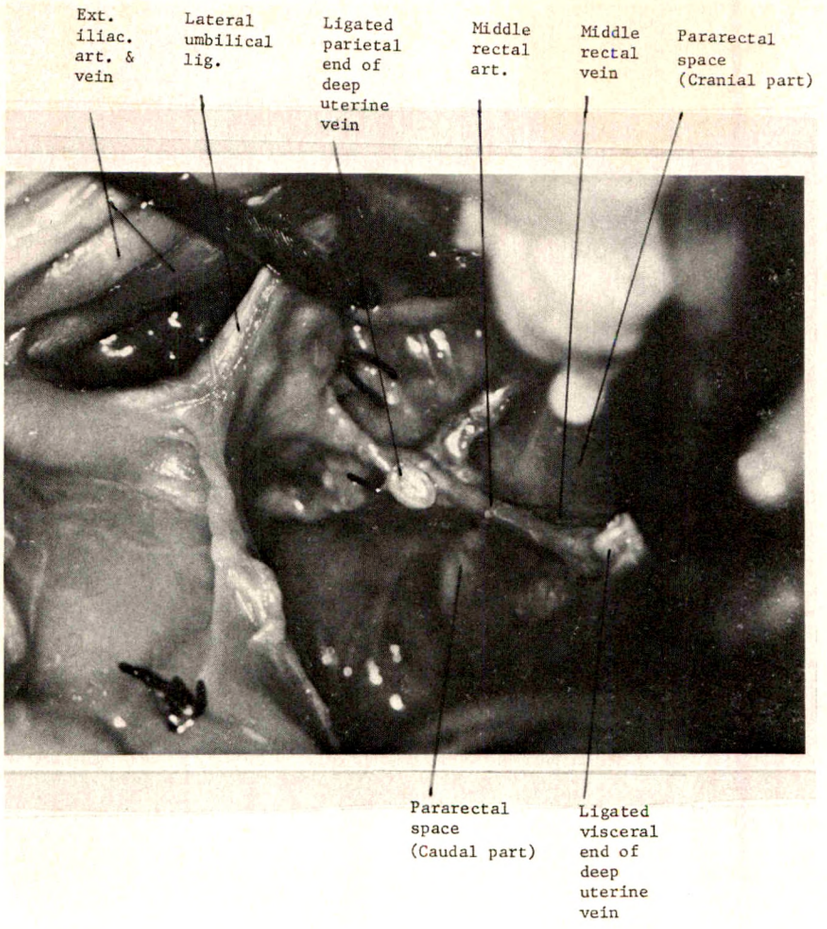

Fig. 6. Middle rectal artery and vein that become visible after severance of deep uterine vein.

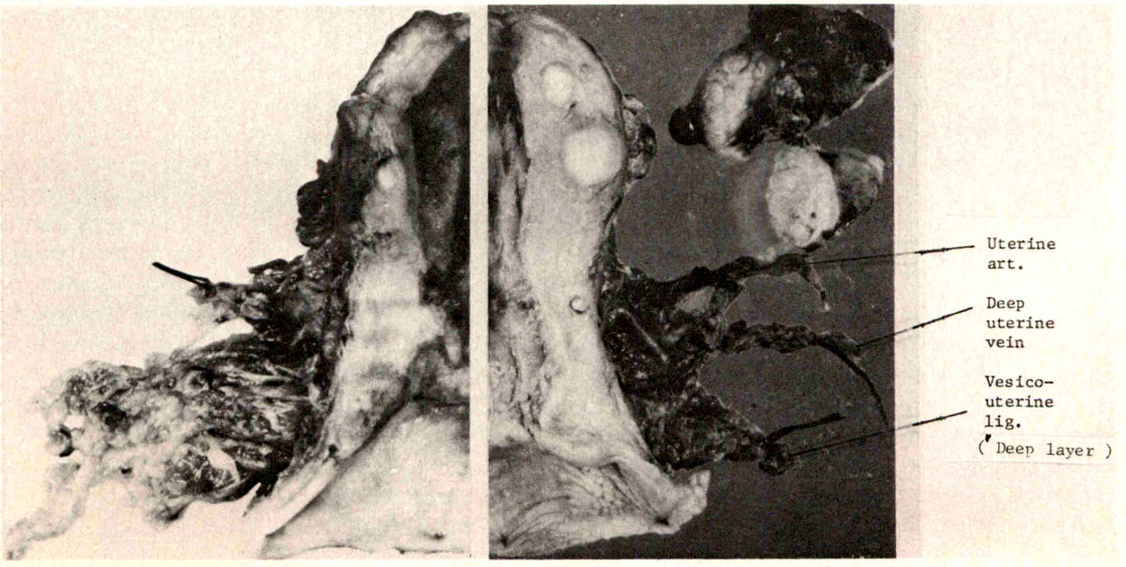

Fig. 7. *Left,* Specimen removed by conventional dissection of the cardinal ligament for cervical cancer. *Right,* Specimen removed by our lateral ligament-preserving method. Conventional technique leaves cut-end mass of ligament in pelvic wall, posing problems for curability.

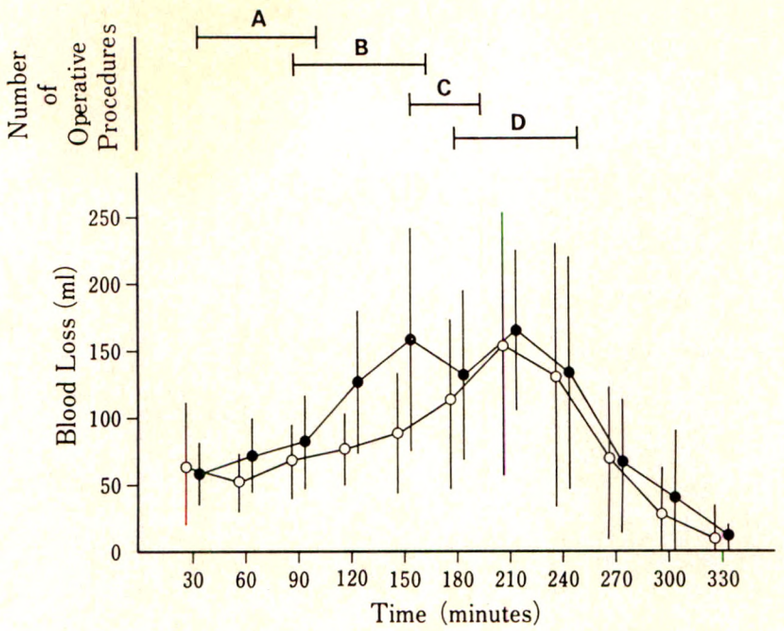

Fig. 8. Comparison of intraoperative bleeding measured at 30-minute intervals, between standard radical hysterectomy (total volume, 1092 ± 359 ml; operation time, 300 ± 32 minutes) and radical hysterectomy with our method (total volume, 850 ± 290 ml; operation time 296 ± 36 minutes). In the latter case blood losses measured at 120 and 150 minutes were 75 ± 27 and 86 ± 44 ml, respectively. These values are significantly smaller than counterparts of 127 ± 51 and 158 ± 83 ml for the former ($p < 0.05$). *A*, Dissection of intrapelvic lymph nodes; *B*, dissection of cardinal ligament; *C*, severance of uterosacral and rectovaginal ligaments; *D*, severance of vesicouterine ligament and paracolpium.

in the vicinity of the pelvic wall, rectum, and anterior surface of the sacrum.

Comment

The difference in the operative procedure of the cardinal ligament dissection among the Wertheim, Meigs, Latzko, and Okabayashi operations is that the former two adopt dissection of the Mackenrodt ligament, whereas the latter adopt deep dissection of the lateral pelvic stalk. The principle of surgical treatment for cancer necessitates extensive removal of affected tissue while maintaining functions of adjacent organs as much as possible. Although the preservation of the lateral ligament seems inconsistent with a radical cure, no progress will be possible without overcoming this dilemma.

Table II shows comparative 5-year survival rates for uterine cancer among the Wertheim and Okabayashi operations as cited from Kobayashi's work,[9] and the Meigs operation.[18] A comparison of the values for these

			I	*II*			
Standard method	20	53.4 ± 8.2	6	14	1.16 ± 0.16	955.8 ± 417.4	1029 ± 359
Our new method	21	52.6 ± 9.5	4	17	1.07 ± 0.19	777.8 ± 642.5	850 ± 290

Table II. Comparison of 5-year survival of patients operated on for cervical cancer between the Wertheim, Okabayashi, and Meigs operation

	Wertheim (%)	*Okabayashi (%)*	*Meigs (%)*
Stage I	64.0	90.9	80.7
Stage II	46.6	43.3	60.7

three operative methods does not always confirm the need for deep pelvic dissection advocated by Okabayashi. In terms of 5-year survival rates for the Wertheim and Okabayashi operations, there was a significant difference for stage I cancers by the Okabayashi operation, but no significant difference for stage II cancers. This was probably because of the dependence of the prognosis on the presence of metastasis in the pelvic lymph nodes irrespective of the operative methods. Our experience further indicated that the Laztko and Okabayashi operations leave the massive severed end of the ligament in the inner aspect of the pelvic wall, posing a problem for recurrence and consequently limiting both operative procedures.

Whereas our operation followed the traditional procedure of the Okabayashi operation, it is characterized by its concise anatomy of the depth of the laminae (so-called cardinal ligament) and by a complete extirpation of the cardinal ligament (the Mackenrodt ligament) from the pelvic wall after exposure and resection of the cardinal blood vessels at the bifurcation of the trunk. In this case, an ultrasonic surgical aspirator is highly contributive. However, when an ultrasonic surgical aspirator is used, complete irrigation and suction throughout the operative field are imperative to eliminate the risk of disseminating viable malignant cells.[19] Furthermore, careful attention should be paid to prevent nerve injury as a result of the ultrasound and heated tip of the ultrasonic surgical aspirator.

In conclusion, our anatomic opinions on the cardinal ligament will also be of interest to surgeons who carry out operations for advanced rectal cancer or gynecologists who perform uterine transplantation in addition to operations for uterine cancer.

Overexpression of HER-2/*neu* in endometrial cancer is associated with advanced stage disease

Prior studies have shown that overexpression of HER-2/*neu* occurs in one third of breast and ovarian cancers and that overexpression is associated with poor prognosis. We used a monoclonal antibody to assess immunohistochemically the level of HER-2/*neu* expression in normal and malignant endometrium. In 24 normal endometrial samples light to moderate (1+ to 2+) staining for HER-2/*neu* was seen in the glands, and there was no variation in intensity of staining during the menstrual cycle. Among 95 endometrial adenocarcinomas, nine (9%) were found to have heavier staining for HER-2/*neu* than was seen in normal endometrium (3+). High expression of HER-2/*neu* was found in 27% of patients with metastatic disease compared with 4% of patients with disease confined to the uterus ($p < 0.005$). High HER-2/*neu* expression also was associated with absence of estrogen receptor ($p < 0.005$) and with increased mortality from cancer. Further studies are needed to determine the significance of HER-2/*neu* overexpression in endometrial cancer. (Am J Obstet Gynecol 1991;164:15-21.)

Key words: Endometrial cancer, HER-2/*neu* oncogene, endometrium

In the past decade the discovery of oncogenes has led to an increased understanding of the biomolecular abnormalities associated with malignant transformation. In this regard it has been shown that viral oncogenes are derived from cellular genes that normally participate in processes of cellular growth and differentiation. In transforming retroviruses and human malignancies these genes are thought to have acquired the ability to elicit malignant transformation by various mechanisms involving either mutation or overexpression. Several of the retroviral oncogenes that have been sequenced have been shown to be homologous with peptide growth factors or their cell membrane receptors. For example, v-*sis* encodes one chain of platelet-derived growth factor whereas v-*erb* B is derived from the gene encoding the epidermal growth factor receptor (c-*erb* B).

In contrast to retroviral oncogenes, the *neu* gene was first identified as the oncogene associated with the development of neuroblastomas in rats exposed to ethyl nitrosourea in utero.[1] In this animal model it has been shown that *neu* is oncogenic because of a single point mutation.[2] Because of the high degree of homology between *neu* and the epidermal growth factor receptor, it is thought that *neu* also encodes a growth factor receptor, although no ligand for *neu* has yet been identified.[3] Although the role of *neu* as a growth factor receptor remains speculative, overexpression of the human *neu* gene, known as HER-2/*neu*, or c-*erb*B2, has been reported to occur in approximately 15% to 40% of breast and ovarian cancers.[4-6] Slamon et al.[4, 5] have shown that overexpression of HER-2/*neu* usually is associated with HER-2/*neu* gene amplification (10% to 30%), whereas approximately 10% of breast and ovarian cancers overexpress HER-2/*neu* in association with a normal gene copy number. In addition, Slamon et al. found that HER-2/*neu* overexpression was associated with aggressive biologic behavior and poor survival in breast and ovarian cancer. A study performed by our group confirmed the association of HER-2/*neu* over-

expression with poor survival in advanced ovarian cancer and demonstrated that this effect is independent of residual tumor volume or histologic grade.[6]

This study is the first to examine HER-2/*neu* expression in normal endometrium and endometrial adenocarcinoma. We used a monoclonal antibody specifically reactive with the external domain of HER-2/*neu* to localize HER-2/*neu* immunohistochemically in frozen tissue sections. The level of HER-2/*neu* expression in endometrial adenocarcinomas was compared with that seen in normal endometrium. In addition, we examined the relationship between the level of expression of HER-2/*neu* and clinicopathologic features of endometrial cancers.

Material and methods

Patients. All 95 patients in this study with endometrial cancer underwent primary surgical therapy at Duke University between 1985 and 1990. Hysterectomy, bilateral salpingo-oophorectomy, and pelvic washings were performed in all cases. In most cases a sample of tumor was submitted for determination of estrogen and progesterone receptor levels. Steroid receptor analysis was performed as described previously with biochemical techniques.[7] Tumors with >7.5 fmol of specific binding per milligram of tissue protein were considered receptor positive. Pelvic and periaortic lymph node sampling was performed as deemed appropriate by the surgeon. In 36 cases lymphadenectomy was not performed for one of the following reasons: presence of extrauterine disease, poor medical condition of the patient, or cancer that was well to moderately differentiated and only minimally invasive. All histologic material from each case was reviewed by a single pathologist, and the histologic type, histologic grade, depth of myometrial invasion, and stage of each cancer (International Federation of Gynecology and Obstetrics) was determined. In addition, a sample of normal endometrium was obtained from the fundal area in 24 women who were undergoing hysterectomy for treatment of benign gynecologic disease. Designations of endometrial dating were assessed by the histologic criteria of Noyes et al.[8]

Monoclonal antibodies. TA-1 is a purified murine monoclonal antibody that was generated by immunization of mice with cells expressing the human HER-2/*neu* molecule[9] (Applied bioTechnology Inc., Cambridge, Mass.). This antibody binds to the extracellular domain of HER-2/*neu* and is not cross reactive with the epidermal growth factor receptor. We found that maximal staining of HER-2/*neu* was achieved with the use of TA-1 at a concentration of 0.5 μg/ml. This concentration of antibody was used to stain all the tissue samples in this study. We used purified mouse immunoglobulin G that is specific for nonhuman tissue (Coulter Immunology, Hialeah, Fla.) at a dilution of 1:100 as a negative control. Antikeratin AE1/AE3 (Boehringer Mannheim Biochemicals, Indianapolis) was used as a positive control.

Immunohistochemistry. All tissue samples were frozen in tissue Tek O.C.T. compound (Ames Division, Miles Laboratories, Elkhart, Ind.) within 30 minutes and stored at −70° C until analyzed. Then 6-μm-thick cryosections were mounted on gelatin-coated slides. The slides were air dried overnight at room temperature to enhance cellular morphologic features. The slides were fixed in acetone for 10 minutes at room temperature and air dried again for 30 minutes. Slides were then washed in phosphate-buffered saline solution three times for 5 minutes. Immunohistochemical staining was performed with Elite Vectastain ABC kit reagents (Vector Laboratories, Burlingame, Calif.) as described previously.[6] For this study staining was performed with the Shandon Cadenza automated immunostainer (Shandon Inc., Pittsburgh). The slides were developed for 4 minutes with the enzyme substrate diaminobenzidine (0.5% diaminobenzidine in 0.5% Tris buffer and 0.6% hydrogen peroxide). The slides then were rinsed for 10 minutes in running tap water, counterstained with 1% methyl green (Sigma Chemical Co., St. Louis), dehydrated, and mounted.

Immunohistochemical localization of HER-2/*neu* was evaluated by means of serial sections. First, a section stained with hematoxylin and eosin was reviewed to evaluate the histologic features. A negative control slide stained with nonspecific mouse IgG was examined to assess nonspecific staining. Next, a positive control slide stained with antikeratin antibody was examined to confirm the presence of viable epithelial or tumor cells in the section. In cases in which the negative and positive controls were not adequate, evaluations were repeated. Finally, the slide in which TA-1 was used as the primary antibody was examined. The intensity of staining was evaluated by two observers using a double-headed microscope. The identify of the patients was not known to the observers while the slides were being scored. The intensity was graded as follows: 0 (staining not greater than negative control), 1+ (light staining), 2+ (moderate staining), or 3+ (heavy staining). Differences between observers were resolved by consensus.

Statistics. Statistical analysis of data in this study was performed with Fisher's two-tailed exact test.[10]

Results

Expression of HER-2/*neu* was examined in normal endometrium from 24 patients (8 proliferative, 11 secretory, 5 postmenopausal). In all cases staining for HER-2/*neu* was confined to endometrial glands and was homogenous (Fig. 1). The intensity of staining in glands ranged from light to moderate (1+ to 2+), but

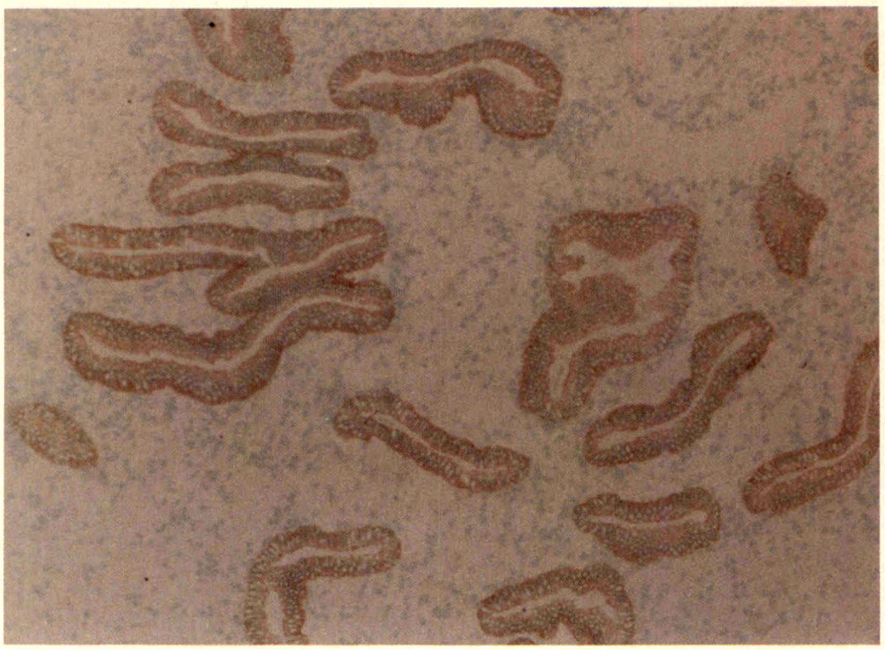

Fig. 1. HER-2/*neu* expression in normal secretory endometrium. Moderate (2+) staining for HER-2/*neu* is seen in endometrial glands.

there was no correlation between menstrual phase and the intensity of staining for HER-2/*neu*. Staining for HER-2/*neu* was not seen in endometrial stroma or myometrium.

The distribution of patients with endometrial cancer by FIGO stage is shown in Table I. Among these 95 patients, 73 (77%) had disease that was confined to the uterus. This included 7 patients with positive peritoneal cytologic results (stage IIIA). Twenty-two patients (23%) had extrauterine disease. In this study we observed the expected relationships between known prognostic factors. For example, increasing histologic grade was associated with a higher incidence of invasion of the outer one third of the uterine wall ($p < 0.05$). Invasion of the outer one third was seen in 7% of patients with well-differentiated cancer, 26% of patients with moderately differentiated cancer, and 43% of patients with poorly differentiated cancer. In addition, increasing histologic grade was associated with a higher incidence of extrauterine metastases ($p < 0.05$). Extrauterine metastases was seen in 7% of patients with well-differentiated cancer, 24% of patients with moderately differentiated cancer, and 43% of patients with poorly differentiated cancer.

Staining for HER-2/*neu* was observed in all 95 endometrial cancers. As in normal endometrium, expression of HER-2/*neu* in cancer was confined to the glandular component. Staining was not observed in the endometrial stroma or myometrium. In the cancer cells staining was strongest on the cell membrane, but cytoplasmic staining also was seen. In a given specimen, the intensity of staining of cancer cells was relatively homogeneous. Light to moderate (1+ to 2+) staining for HER-2/*neu*, similar to normal endometrium, was seen in 86 cases (91%) (Fig. 2, *A*) whereas heavy (3+) staining was seen in 9 cases (9%) (Fig. 2, *B*). There was a significant relationship between heavy staining for HER-2/*neu* and the presence of metastatic disease ($p < 0.005$). Among the 73 patients with disease confined to the uterus (including 7 with positive peritoneal cytologic results), 3 patients (4%) had heavy staining for HER-2/*neu*. In contrast, 6 of 22 patients (27%) with extrauterine metastases had heavy staining for HER-2/*neu*. Among the 22 patients with metastatic disease, heavy staining for HER-2/*neu* was seen more frequently in patients with intraperitoneal metastases (42%) than in those patients in whom metastasic disease was confined to lymph nodes (10%). In two cases in which peritoneal metastases were present, HER-2/*neu* expression was evaluated in both the primary tumor and one metastatic site. In both cases the intensity of staining was the same when the two sites were compared. This included one case in which normal (1+) HER-2/*neu* expression was seen and one case in which high (3+) HER-2/*neu* expression was seen.

Among the 95 cancers, 71 (74%) were histologically endometrioid, 12 (13%) were adenosquamous, and 12 (13%) were papillary serous. High (3+) HER-2/*neu* expression was noted in 8% of endometrioid cancers (6 cases) and 25% of papillary serous cancers (3 cases)

Table I. Relationship between FIGO stage and HER-2/neu expression in endometrial cancer

FIGO stage	*Total No. of patients*	*High HER-2/neu expression*	
		No. of patients	*%*
IA. Limited to endometrium	12	1	8
IB. Invades inner half of myometrium	38	2	5
IC. Invades outer half of myometrium	12	0	0
IIA. Endocervical glands involved	1	0	0
IIB. Cervical stroma involved	3	0	0
IIIA. Positive cytologic results	7	0	0

IVA. Bowel or bladder invasion	0	—	—
IVB. Distant metastases	12	5	42

(p = 0.08). None of the 12 patients with adenosquamous cancers had high levels of HER-2/*neu* expression.

The relationship between a high level of HER-2/*neu* expression and other known prognostic factors is shown in Table II. Although increasing histologic grade and depth of myometrial invasion were associated with a higher incidence of high HER-2/*neu* expression, these relationships were not statistically significant. For example, only 2 of 51 patients (4%) with cancer confined to the endometrium or invading the inner one third of the myometrium had high HER-2/*neu* expression compared with 7 of 44 patients (16%) with deeper invasion (p = 0.08). With respect to steroid receptor status, there was a significant relationship between HER-2/*neu* expression and estrogen receptor status (p <0.005). All 8 cancers with high levels of HER-2/*neu* expression in which steroid receptor levels were determined were estrogen receptor negative (Table II). With respect to progesterone receptor status, 4 of 8 cancers with high HER-2/*neu* expression in which progesterone receptor levels were determined were progesterone receptor positive.

In this study we found that high HER-2/*neu* expression was associated with an increased incidence of death from persistent or recurrent cancer (Table III). Overall, among the 86 patients whose cancers had light to moderate staining for HER-2/*neu*, 10% are dead of disease, compared with 56% of the 9 patients whose cancers had heavy staining. Among the three patients with stage I disease who had high HER-2/*neu* expression, one has developed recurrent disease. If only patients who presented with metastatic disease are considered, 5 of 16 patients (31%) whose tumors had light to moderate staining for HER-2/*neu* are dead of disease while all 6 patients whose tumors had heavy staining for HER-2/*neu* are dead of disease. Since most of the patients in this study underwent operation during the past 2 years, survival data are not mature enough to present as survival curves.

Comment

Although HER-2/*neu* is structurally similar to the epidermal growth factor receptor, we found that the distribution of these two cell surface molecules in the normal human uterus differs significantly. Previously, we and others have shown that epidermal growth factor receptor is expressed by endometrial glands, endometrial stromal cells, and myometrium.[13, 14] In contrast, in this study we found that expression of HER-2/*neu* in the uterus is confined to endometrial glands. Similarly, immunohistochemical studies of *neu* expression in the rat also have shown that *neu* is expressed primarily by epithelial cells.[13] Like epidermal growth factor receptor, however, we saw no cyclic variation in the intensity of staining for HER-2/*neu* during the menstrual cycle. Further studies are needed to clarify the physiologic significance of the differences in distribution of epidermal growth factor receptor and HER-2/*neu* in the uterus and to determine the role of these receptors in processes of normal growth and development in this organ.

Prior studies of HER-2/*neu* in human cancers have shown that overexpression of structurally normal HER-2/*neu* protein occurs in approximately one third of breast and ovarian adenocarcinomas.[4-6] This is the first study to examine HER-2/*neu* expression in a significant number of endometrial cancers. We found that 9% of endometrial adenocarcinomas had heavier staining for HER-2/*neu* than was observed in normal endometrial glands. Although high HER-2/*neu* expression was uncommon (4%) among early stage cancers, 27% of cancers that had metastasized were found to have have HER-2/*neu* expression. Interestingly, the highest incidence of HER-2/*neu* overexpression (42%) was found in patients whose tumors had spread intraperitoneally (stage IVB), similar to ovarian cancer. As in breast[4, 5] and ovarian cancer,[5, 6] HER-2/*neu* overexpression was found to be associated with poor prognosis in endo-

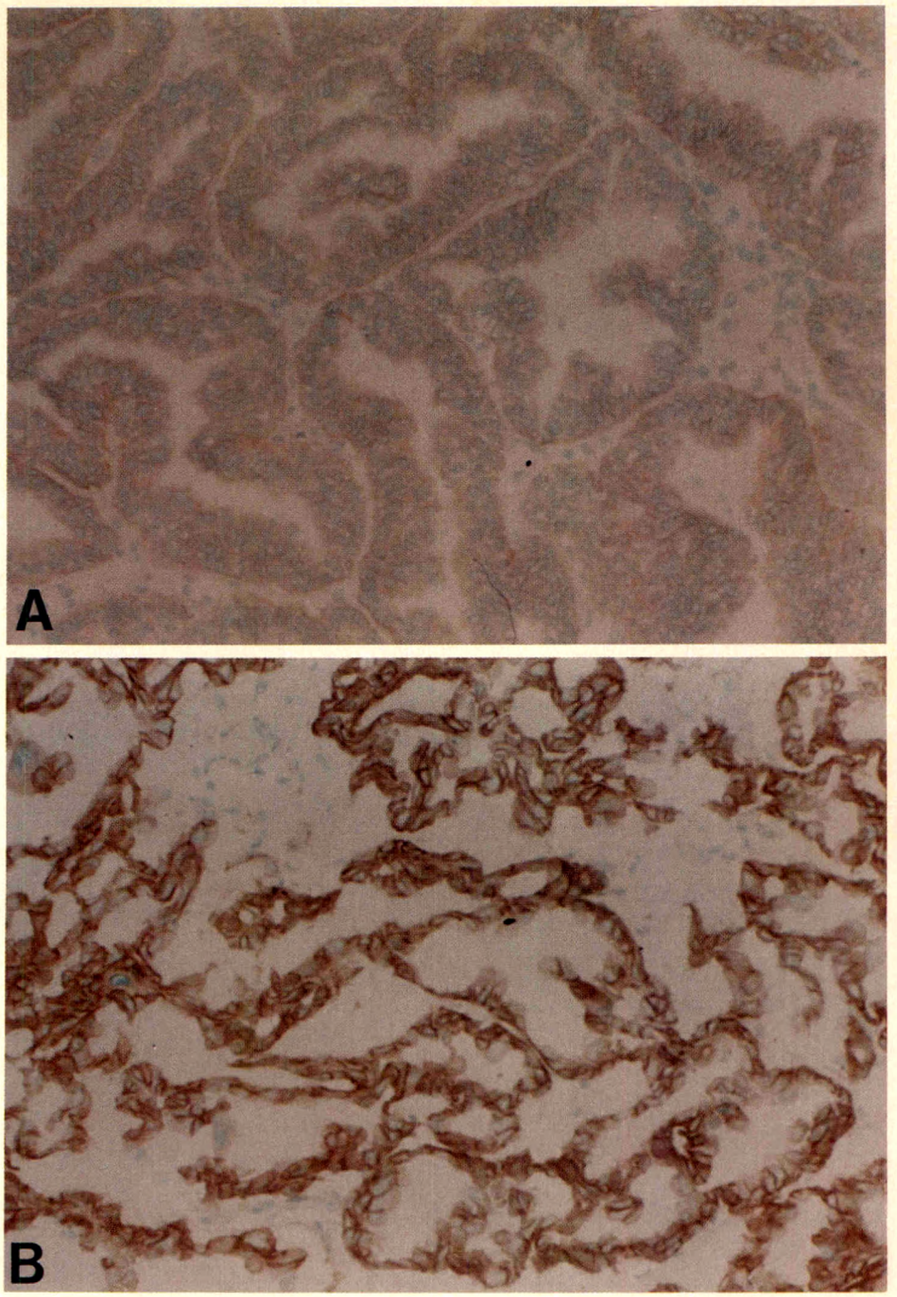

Fig. 2. HER-2/*neu* expression in endometrial cancer. **A**, Well-differentiated endometrial cancer with light (1+) staining for HER-2/*neu*. **B**, Moderately differentiated endometrial cancer with heavy (3+) staining for HER-2/*neu*.

metrial cancer. Among the 9 patients with HER-2/*neu* overexpression, one of three with disease that initially was confined to the uterus has developed recurrent disease, and all 6 patients who presented with metastases are dead of disease.

In breast cancer several studies have shown that expression of epidermal growth factor receptor and estrogen receptor is inversely related and that epidermal growth factor receptor expression is associated with poor prognosis.[14, 15] However, no relationship between HER-2/*neu* overexpression and estrogen receptor status has been noted in breast cancer.[16] Although endo-

metrial cancers, like breast cancers, frequently express estrogen receptor and may be responsive to endocrine therapy, in an earlier study of endometrial cancer we did not find a relationship between expression of epidermal growth factor receptor and estrogen receptor. In the present study, however, we did find a strong inverse relationship between high HER-2/*neu* expression and estrogen receptor status. In all cases in which high HER-2/*neu* expression was seen, estrogen receptor was absent. These results suggest that although both breast and endometrial cancers frequently maintain expression of steroid receptors, they may differ with respect to which oncogenes are involved in their pathogenesis. It is possible that increased HER-2/*neu* expression in estrogen-receptor-negative endometrial cancers reflects escape from normal steroid hormone–related growth regulatory pathways.

HER-2/*neu* overexpression appears to be an important prognostic factor in female reproductive cancers (breast, ovary, endometrium). If assessment of HER-2/*neu* expression is to be used in the clinical management of patients, however, a practical and reliable method must be available. In this and other studies,[6] we have used immunohistochemical techniques to compare the intensity of staining for HER-2/*neu* in frozen sections of cancers with that seen in frozen sections of the normal organ from which the cancer arose. The advantage of this method is that it allows direct assessment of HER-2/*neu* expression at a cellular level. Other methods in which tissue homogenates are used to measure levels of deoxyribonucleic acid, ribonucleic acid, or protein all are subject to error because of differences in the proportion of cancer cells relative to stromal elements in tumor samples. On the other hand, although results obtained with immunohistochemical techniques have been shown to correlate well with the Southern, Northern, and Western techniques,[5] immunohistochemical assessment has been only semiquantitative in the past.

Recently, however, a computerized image analysis program has been developed that allows quantitative assessment of immunohistochemical staining for HER-2/*neu*.[17] Cell lines with both normal and high expression of HER-2/*neu* are used as calibration standards so that day-to-day variation in staining intensity can be accounted for. The intensity of staining of cancer specimens is interpreted relative to that of the cell lines with known normal or high HER-2/*neu* expression. Since the antigenicity of HER-2/*neu* can be altered by paraffin embedding, however, it has been suggested that frozen tissue samples are most suitable for immunohistochemical evaluation. Presently, we are conducting a prospective study of the prognostic value of HER-2/*neu* in gynecologic cancers with the use of quantitative image analysis of immunohistochemical staining for HER-2/*neu* in frozen sections.

The precise significance of the relationship between HER-2/*neu* overexpression and the biologic behavior of female reproductive cancers (breast, ovary, endometrium) remains unknown. Several groups of investigators now are studying the role of HER-2/*neu* in neoplasia to determine if HER-2/*neu* overexpression is directly involved in, rather than merely associated with, the biomolecular events involved in evolution of cells with metastatic potential. If HER-2/*neu* overexpression is found to be a causal event in the process of tumor progression, this would suggest that the favorable prognosis of early stage endometrial cancer may be due, in part, to favorable tumor biologic characteristics, as reflected by the low incidence of HER-2/*neu* overexpression, rather than merely to early clinical detection. Conversely, ovarian cancers, which frequently overexpress

HER-2/*neu*, may be highly lethal not only because of their insidious clinical presentation but also because of more aggressive biologic behavior, as reflected by a high incidence of HER-2/*neu* overexpression.

We thank Regina Whitaker and B.J. Kerns for their expert technical assistance.

Early neonatal mortality and cesarean delivery in Mexico City

Jose L. Bobadilla, MD, PhD, and Godfrey J.A. Walker, MD, MFCM
Mexico City, Mexico, and London, England

The relationship between cesarean delivery and neonatal mortality is presented with information from 292 early neonatal deaths (cases) and 3098 survivors (controls) born in 25 hospitals in Mexico City during the summer of 1984. The overall rate of cesarean delivery was 27%. Variations between health agencies and different social groups were not related to obstetric risk, suggesting that a sizable proportion of the operations were probably unjustified. Babies of normal birth weight (≥2500 gm) delivered by cesarean section were 2.5 times more likely to die in the early neonatal period compared with vaginally delivered babies of the same weight. The excess of mortality could not be explained by the effect of maternal characteristics or complications or by differences in birth weight or gestational age. It is suggested that the conditions under which the operation was performed probably explain the increased risk of early neonatal death. It is likely that poor quality of resuscitation and respiratory care are implicated in the link between "unnecessary" cesarean section and early neonatal mortality. (AM J OBSTET GYNECOL 1991;164:22-8.)

Key words: Cesarean delivery, early neonatal mortality, Mexico City

Cesarean delivery rates have increased steadily in many countries over the past two decades.[1-7] Very high rates have been reported from Latin America ranging from 20% in public hospitals in Mexico City[8] to 27% in southern Brazil[9] and 49% in Campinas, Brazil.[2]

The reasons for the rise in cesarean section rates are complex and likely to vary between different places.[10, 11] Two major factors that influenced obstetricians are improvements in the safety of the procedure in terms of reduced maternal morbidity and mortality[12] and claims that increased rates of cesarean section have led to a decline in perinatal mortality.[13, 14]

Other factors that contributed to the rise in cesarean delivery include the availability of more precise technology to diagnose fetal distress,[15] the snowball effect produced by the policy of "once a section, always a section,"[16] higher rates of induction of labor,[17] higher proportions of women delivered of infants in large hospitals and of third-party payments for deliveries,[12, 18] and the practice of defensive obstetrics.[3, 19] The wide variation in rates of cesarean section between and within countries raises questions as to the effectiveness of the procedure in improving the prospects of early neonatal survival.[5, 20, 21]

Even in countries with adequate resources and good quality medical care, early neonatal mortality rates among cesarean deliveries are seldom reported separately and are often excluded from discussions on the benefits and risks of cesarean section.[22]

This study examines the relationship of the outcome of obstetric care in terms of early neonatal mortality (controlled for maternal risk status) to the adequacy of care, specifically cesarean delivery, provided at hospitals in Mexico City.

In the metropolitan area of Mexico City there are annually over 310,000 births of which about 85% occur in hospitals (unpublished data). Hospital care is provided through three systems: (1) the public assistance system of the Ministry of Health and Federal District Health Services; (2) the Social Security system of which the Mexican Institute of Social Security and the Institute of Social Security and Services for Employees of the Federal Government are by far the largest; and (3) independent private practice. The various systems are known to cater to different communities. In general, the poorest persons use the public assistance, manual and public workers use Social Security, and the more affluent use the private practice option.

Material and methods

Representative maternity units in hospitals of the three medical care systems were included in the study. Seven public assistance hospitals (covering an estimated 74% of births in this system), 14 Social Security hospitals (seven from each of the two major agencies and covering about one third of the births in this system), and the four private hospitals that reported over 2000 deliveries per annum were selected.

Over a 14-week period during the summer of 1984 information was collected on a sample of women delivered of infants in the study hospitals, the babies who survived to the seventh day after delivery, and all

early neonatal deaths. Early neonatal deaths were identified by following up all babies to the seventh day after delivery. To control for the possible confounding effect of birth weight, babies were considered in two groups: normal birth weight (NBW), those weighing ≥2500 gm, and low birth weight (LBW), those weighing <2500 gm. Inasmuch as the early neonatal death rate is high among LBW babies (20%), the case-control approach was not suitable and all LBW babies were included in the study. For NBW babies a case-control method was used; every thirtieth NBW baby born in the study hospitals who survived the early neonatal period was systematically selected as a control. Details of the care received by case and control subjects were obtained by interview with the mother and from review of all medical records. Multiple births, babies who weighed <1000 gm, and those with lethal congenital malformations were excluded from the analyses of the relationship between cesarean section and early neonatal mortality.

To control for the confounding effect of factors other than birth weight an index of perinatal risk was used similar to that of Chamberlain et al.[23] (see Table I). This index was constructed for each mother and the sum of the values of the variables was calculated for each woman. The women were classified as low risk if the sum added to less than three, medium if three to seven, and high for all those with a score above seven. The risk score was able to successfully categorize women into three groups with significantly different outcomes (early neonatal mortality) (see Table II).

For LBW babies the ratio of the mortality rates between exposed and unexposed (to cesarean delivery) was used as the measure of association and for NBW babies the odds ratio of exposure between control and case subjects was used. To control for the confounding effects of many variables (e.g., risk status, parity, years of schooling) in the analysis of the association between early neonatal death and cesarean section, indirect standardization and the Mantel and Haenszel procedure[24] were used for LBW and NBW babies, respectively.

Information from hospital records was used to estimate the whole-time equivalents of interns, residents, and specialist obstetricians working in the maternity wards of the study hospitals.

Results

Over the 14-week period 32,701 babies were born in the 25 hospitals. There were 518 early neonatal deaths for a mortality rate of 16.0 per 1000 live births. Of the 32,329 babies born alive 3103 (9.6%) weighed <2500 gm. Among the LBW babies, 240 early neonatal deaths and 2192 survivors were included and for the NBW babies, 52 deaths and 906 controls were included. The remaining 226 early neonatal deaths were excluded because the birth weight was <1000 gm or they had a lethal congenital malformation.

Babies of normal birth weight classified as low risk if score is less than three, medium risk if three to seven, and high risk if over seven.

*Weightings taken from Chamberlain et al.[23]

Over one fourth (27%) of deliveries were by cesarean section and this was more common among women in private hospitals (39%) than those in Social Security (25%) or public assistance (21%). Cesarean delivery was more frequent among LBW (33%) than in NBW babies (23%).

For the LBW babies the early neonatal mortality rate was 36 times higher in the high-risk group as compared with the low-risk group and three times that in the medium-risk group. Among NBW babies the mortality rate was more than three times higher in the high-risk than in the medium-risk group (there was only one death among the NBW low-risk babies) (see Table II). Paradoxically the cesarean section rate was only moderately related to the risk score (high risk, 33%; medium risk, 29%, and low risk, 26%).

In both birth weight groups babies delivered by cesarean section were more likely to die in the early neonatal period. This statistically increased relative risk (RR) of mortality persisted after adjustment for risk status (Table III).

It is difficult to estimate the extent to which the excess of early neonatal deaths among cesarean section, as compared with vaginally delivered babies, was a result of the "medical" condition that prompted the decision to undertake a cesarean section. However, this is unlikely to be confounded by other factors because birth weight was controlled for by stratification into two groups. In addition, the maternal risk score includes

several factors strongly associated with the prevalence of medical conditions taken as indications for cesarean delivery. That the RR did not significantly change after adjustment for maternal risk suggests that mothers were similar in the two groups (cesarean and vaginal deliveries). The implication of this is that the excess of early neonatal mortality in cesarean births cannot be explained by differences in maternal age, parity, education, obstetric history, diabetes, height, and marital status, or probably by differences in medical conditions associated with these factors.

To further explore whether the marked excess of early neonatal mortality among NBW babies was confounded by other factors additional bivariate adjustments of relative risks were undertaken. The results of these analyses are summarized in Table IV.

The adjustment for maternal risk gave a higher RR of early neonatal mortality for cesarean deliveries for medium-risk babies than those in the high-risk group. The maternal age group with the lowest overall risk of early neonatal mortality (20 to 29 years) had the greatest excess associated with cesarean section. The adjusted RR for parity was higher than the crude RR, suggesting that parity has some negative confounding effect; whereas the adjusted RR for gestational age was slightly lower, indicating that some of the excess mortality is probably a result of differences in gestational age between the two groups of babies.

The RR of early neonatal mortality for babies delivered by cesarean section was considerably higher in public assistance (4.76) than in Social Security hospitals (2.07). Although the cesarean section rate was high (39%) in private hospitals, there were no deaths among babies delivered this way. It is widely recognized that a far higher porportion of births in public assistance than in Social Security hospitals are supervised by interns and residents as opposed to specialists. Social Security hospitals have more than 1.5 times the specialists and far fewer interns than do public assistance hospitals (Table V). Unfortunately relative risks of mortality could not be estimated by type of birth attendant because of incomplete information.

The RR of early neonatal mortality for babies delivered by cesarean section from mothers with spontaneous onset of labor was 3.38 [confidence limits (CL), 1.82, 6.27], higher than for those born to mothers whose labor was induced 1.96 (CL, 0.39, 10.10). About 12% of the cesarean deliveries were elective and the RR of early neonatal mortality for elective cesarean section compared with emergency cesarean section was 0.80 (CL, 0.22, 2.85).

For babies who weighed ≥2500 gm, significantly

raised relative risks of early neonatal mortality were found among those delivered by cesarean section. A striking finding was that babies with the lowest absolute risk of early neonatal mortality (those weighing 3000 to 3499 gm) had the highest relative risk of dying in the early neonatal period when delivered by cesarean section. The significantly raised relative risks of early neonatal mortality for babies who weigh ≥2500 gm when delivered by cesarean section persisted even after controlling for major obstetric, social, and biologic risk factors.

The overall attributable risk of early neonatal mortality associated with cesarean delivery, that is the rate of early neonatal mortality among cesarean births minus the rate among vaginally delivered babies, was 13.9 (i.e., 23.1 − 9.2): for LBW babies, 50.4 (i.e., 138.0 − 87.6) and for NBW babies, 4.3 (i.e., 6.5 − 2.2). The etiologic fraction of early neonatal mortality associated with exposure to cesarean delivery was 27%, being lower for the LBW (10%) than the NBW babies (32%).

The relative risk of early neonatal mortality among cesarean-delivered babies compared with those delivered vaginally increased steadily with birth weight except for the heaviest babies (>3500 gm) (see Fig. 1). The largest relative risk was for babies who weighed 3000 to 3499 gm at 5.66 (CL, 2.41, 13.28). These babies, who had the best chances of neonatal survival, account for 42% of all babies born and 38% of all cesarean deliveries. Almost one fourth of the babies in this birth weight group were delivered by cesarean section giving an etiologic fraction of 42% associated with cesarean section.

The cesarean section rate was 87% in breech as opposed to 22% in cephalic presentations. The relative risk of early neonatal mortality by cesarean delivery was 0.30 (CL, 0.05, 1.86) for breech presentations and 3.42 (CL, 1.84, 6.38) for cephalic presentations.

Comment

Over the past 20 or so years cesarean section has become an increasingly common form of delivery.[1-9] The apparent safety of the procedure under optimal conditions has led to the suggestion that all women who have not been delivered of infants by term should have a "prophylactic" cesarean delivery.[25] The major concerns about high and increasing rates of cesarean section principally centered around the costs and neonatal morbidity.[21, 26-29]

It is accepted that the procedure is efficacious in certain defined situations, but as with all technology

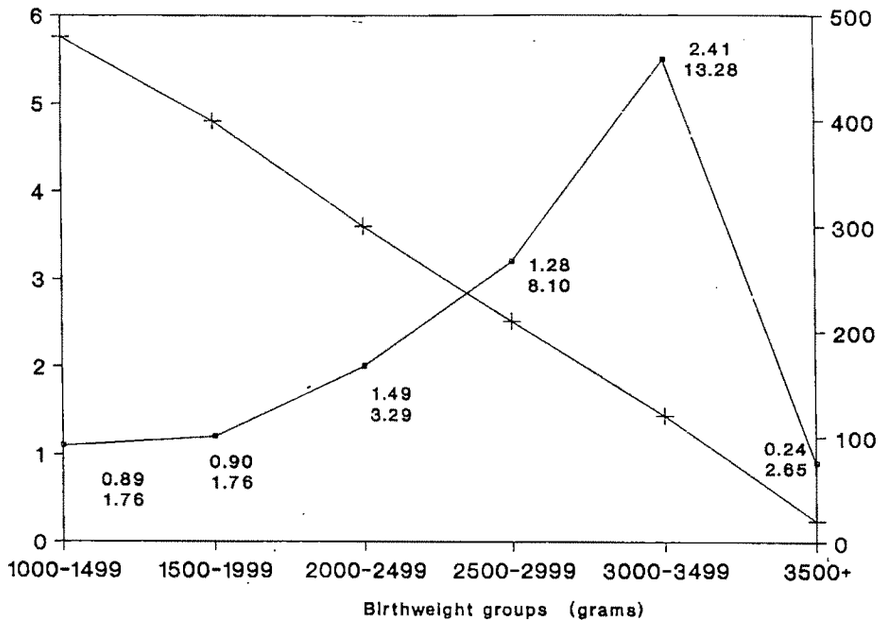

Fig. 1. Early neonatal mortality rate and relative risk of early neonatal death for babies delivered by cesarean section by birth weight group. Right-hand scale is early neonatal mortality rate per 1000 live births. Left-hand scale is relative risk of death for babies delivered by cesarean section compared with vaginally delivered babies; numbers are 95% confidence intervals for relative risk.

its effectiveness should be questioned when used without clear indications and in the absence of quality assurance programs. Recognition of these issues in the United States led the National Institute of Child Health and Human Development to organize a consensus conference on cesarean childbirth in 1980.[30] This concern has been reflected elsewhere with more aggressive efforts to reduce the proportion of deliveries carried out by cesarean section[7] and has been shown to be effective where high standards of care are provided.[31, 32]

Cesarean delivery has been shown to be associated with low Apgar score,[21] and a raised incidence of hyaline membrane disease[28] and respiratory distress syndrome.[27, 29, 33] The main complication among mature NBW babies is delayed onset of respiration.[34] The present study confirms Usher's original work[35] carried out in 1964, which showed an increased risk of respiratory distress syndrome in infants delivered by cesarean section. It is possible that the increased incidence of respiratory distress syndrome and delay in spontaneous respirations among babies delivered by cesarean section is a result of deficient secretion of hormones because of a lack of the physical stress that normally occurs during vaginal delivery.[29, 36-38]

In Mexico City cesarean delivery is relatively common, ranging from 39% of births in large private hospitals to 21% in public assistance hospitals, this is in contrast to the percentages of high-risk babies who were 8% and 18%, respectively. This study showed that it was only in breech presentations that the RR of early neonatal mortality associated with cesarean delivery was lower than that for vaginally delivered babies. Others have reported similar findings.[39, 40]

The association of the health system with the high RR of early neonatal mortality associated with cesarean section in NBW babies in this study was highly significant. This probably reflects the situation with regard to several aspects of quality of care. In the public assistance hospitals the decision to undertake a cesarean section is usually made by a resident in obstetrics with limited training, and support in anesthesia and pediatrics is provided by colleagues also with inadequate experience.

In private hospitals there are obvious financial incentives for obstetricians to resort more readily to cesarean delivery than are justified on strict obstetric criteria.[9] In public hospitals this does not apply, but given the high status of the private sector it is possible that practice there sets a standard that influences the threshold at which cesarean section is thought appropriate. However, there are other factors that encourage high rates of cesarean section: many hospitals are staffed mainly by residents with limited experience, their supervision is frequently inadequate, and it is consequently not surprising that their threshold to carry out a cesarean section is low. It removes the necessity to

monitor the progress of labor and gives obstetricians greater control over the timing of deliveries.

In Mexico City with the absence of quality assurance systems there are limited checks on whether the operation was medically justified. This study suggests that in this situation in which cesarean section rates are high and many cesarean deliveries are carried out under suboptimal conditions with no clear medical indications to deliver infants of normal birth weight with a low overall risk of early neonatal mortality, might result in unnecessary neonatal deaths. In view of this there is a pressing need to define objective criteria for undertaking cesarean sections and to institute review procedures of the circumstances that surround cesarean sections such as those described by Myers and Gleicher[32] and Porreco[11] from the United States.

We thank the many mothers, doctors, nurses, and administrators without whose cooperation this study would not have been possible. The assistance of Ernesto Díaz del Castillo, Carlos Lozano, Samuel Karchmer, Jose Narro, and Jaime Sepulveda was invaluable in obtaining access to the hospitals of the various health schemes.

Julio Frenk, Sergio Ponce de Leon, and Malaquias Lopez Cervantes gave invaluable comments on earlier drafts of this article.

The effect of tetracycline on levels of oral contraceptives

Ana A. Murphy, MD,[a] Howard A. Zacur, MD, PhD,[a] Patricia Charache, MD,[b] and Ronald T. Burkman, MD[c]

Baltimore, Maryland

Despite the widespread use of tetracycline for treatment of dermatologic disorders and sexually transmitted diseases, the pharmacodynamics of oral contraceptive use in the presence of tetracycline has not been studied. Seven normal women ingested an oral contraceptive containing ethinyl estradiol 35 μg and norethindrone 1 mg in the follicular phase of the menstrual cycle. On day 0 baseline ethinyl estradiol and norethindrone levels were obtained at 0, ½, ¾, 1, 2, 4, 12, and 24 hours after oral contraceptive administration. On day 1 tetracycline 500 mg was given orally every 6 hours while the oral contraceptive was continued. Tetracycline, ethinyl estradiol, and norethindrone levels were determined at the same time intervals as on day 0. Oral contraceptive and tetracycline were continued for up to 10 days, and additional concentrations of ethinyl estradiol, norethindrone, and tetracycline were determined between days 5 and 10. Four additional normal women ingested tetracycline for 5 to 10 days. Tetracycline levels were determined at the time intervals noted above on day 1 and days 5 to 10. No significant decrease in plasma ethinyl estradiol or norethindrone concentration was seen with either short-term (24 hours) or long-term (5 to 10 days) ingestion of tetracycline. Similarly, levels of tetracycline do not significantly decrease with ingestion of a low-dose oral contraceptive. (Am J Obstet Gynecol 1991;164:28-33.)

Key words: Oral contraceptives, tetracycline, ethinyl estradiol, norethindrone

The controversial topic of drug interaction between oral contraceptives and antibiotics dates back to 1971 when Reimers and Jeyeck[1] noted an increase of abnormal vaginal bleeding in oral contraceptive users receiving rifampin and other antituberculous drugs. Two years later, Nocke-Finck et al.[2] reported that 5 of 88 rifampin–oral contraceptive users became pregnant while 62 of the remaining women experienced abnormal bleeding or amenorrhea. Since then there have been numerous case reports of oral contraceptive users becoming pregnant while receiving ampicillin, tetracycline, chloramphenicol, griseofulvin, sulfonamides, and others.

The postulated mechanism by which broad-spectrum antibiotics interfere with oral contraceptives is alteration of the gut flora so that less estrogen is reabsorbed. It is, however, very uncertain whether broad-spectrum antibiotics such as ampicillin and tetracycline decrease the efficacy of oral contraceptives. Joshi et al.[3] have demonstrated no decrease in area under the curve or in peak or mean levels of the oral contraceptive components when women ingest ampicillin or metronidazole.

Tetracycline is a drug of choice for the outpatient treatment of pelvic inflammatory disease and some other sexually transmitted diseases. Most patients need a 7- to 10-day course of this antibiotic; often times many

are also using oral contraceptives. Although the question of interaction between these two drugs is commonly brought up, there are no studies that definitively address this point. Only case reports suggest possible interaction.[4] The purpose of this study is to determine whether tetracycline affects contraceptive steroid levels. The effect of oral contraceptives on tetracycline levels also will be assessed.

Material and methods

Subjects. Seven healthy, normally menstruating women aged 18 to 35 were studied. None had received steroid treatment within the last 3 months before the study. The study protocol was approved by the internal review board and informed consent was obtained from each volunteer. An oral contraceptive containing 35 μg of ethinyl estradiol and 1 mg of norethindrone was begun within 1 to 5 days of the onset of the menstrual cycle. Serum samples for ethinyl estradiol and norethindrone were obtained on day 0 between 7 and 9 AM, before oral contraceptives were begun, and ½, ¾, 1, 2, 4, 12, and 24 hours after ingestion of the oral contraceptive. The next day (day 1), at the same time the oral contraceptive pill was ingested the previous day, another oral contraceptive pill was ingested in conjunction with 500 mg of tetracycline hydrochloride (Lederle Laboratories, Pearl River, N.Y.). The tetracycline was continued at that dose every 6 hours. Serum samples for ethinyl estradiol, norethindrone, and tetracycline were drawn at the same time intervals cited. The patients continued to ingest the oral contraceptive pill each morning and tetracycline every 6 hours. Five to 10 days later, serum samples were obtained at the time intervals indicated. One patient failed to finish the study because of gastrointestinal side effects.

Four healthy, normally menstruating women aged 18 to 35 were studied as tetracycline controls. None had received steroid treatment within the 3 months before the study. Tetracycline hydrochloride 500 mg was begun within 1 to 5 days of the onset of the menstrual cycle. The tetracycline was continued every 6 hours for 5 to 10 days. Serum samples for tetracycline were obtained before the antibiotic was begun and at the time intervals noted previously for ethinyl estradiol, norethindrone, and tetracycline. The sampling was repeated 5 to 10 days later. One patient failed to finish this part of the study because of gastrointestinal effects. All sera were stored at −20° C until analysis.

Assay methods. Ethinyl estradiol and norethindrone were quantified by direct radioimmunoassay with a modification of the procedures described by Stanczyk et al.[5, 6] Tritiated ethinyl estradiol and norethindrone were obtained from New England Nuclear (Boston). The ethinyl estradiol antibody was obtained from C. Edgar Cook (Research Triangle Institute, Research Triangle Park, N.C.). The norethindrone antibody was graciously donated by Ing Nieuweboer (Schering AG, Berlin). The intraassay coefficient of variation was 10.6% for ethinyl estradiol and 11.6% for norethindrone. The interassay coefficient of variation was 18.7% for ethinyl estradiol and 12.5% for norethindrone. The sensitivity of the assay was 12 pg/ml for ethinyl estradiol and 0.15 ng/ml for norethindrone.

Tetracycline serum samples were assayed by an agar well diffusion assay.[7, 8] Two milliliters of a 1:100 dilution of *Bacillus cereus* spore suspension (Difco Lab., Detroit) and 23 ml of antibiotic Medium 1 (Difco) for each 150 mm polystyrene petri plate were used.

Standards and controls were prepared with tetracycline hydrochloride standard powder (Lederle), which was reconstituted in sterile deionized water and diluted in heat-inactivated pooled normal human serum (Whittaker M.A. Bioproducts, Walkersville, Md.) to yield the following standard concentrations: 1, 2, 4, 8, and 16 μg/ml. A control serum sample containing 6 μg/ml of tetracycline was prepared in 100 ml aliquots, stored at −70° C, and thawed on the day of use.

Five-microliter samples of standard, control, or patient serum were placed into 3 mm wells in the bioassay plate. Standards were run in duplicate; control and patient sera were run in triplicate assays per plate. The plates were incubated overnight at 37° C and the zones of inhibition were measured. Concentrations for patients were determined from a plot of the log of the standard concentration vs the zone diameters (in millimeters). The standard curve correlation of coefficients ranged from 0.990 to 1.000. Coefficient of variation for the 6 μg/ml control serum was 7.7%. Therapeutic levels of tetracycline are 2 to 4 μg/ml.

Statistical methods. Repeated measures analysis of variance and covariance was used for analysis of the effects of tetracycline on ethinyl estradiol and norethindrone levels (BMDP Statistical Software, Inc., Los Angeles). Area under the 4-hour curve was calculated with RSI software (BBN Software Products, Cambridge, Mass.) and peak levels were compared at days 0, 1, and 5 to 10. Multiple range testing was done once significance was reached, with analysis of variance. The subject who did not complete the study was not included in the analysis.

The effects of oral contraceptives on tetracycline levels were examined by a two-way analysis of variance. Tetracycline 4-hour area under the curve of the patients using oral contraceptives and tetracycline (day 1 and days 5 to 10) were compared with the control subjects who received tetracycline alone (day 1 and days 5 to 10). Peak levels of tetracycline in these two groups were compared by means of the same statistical test.

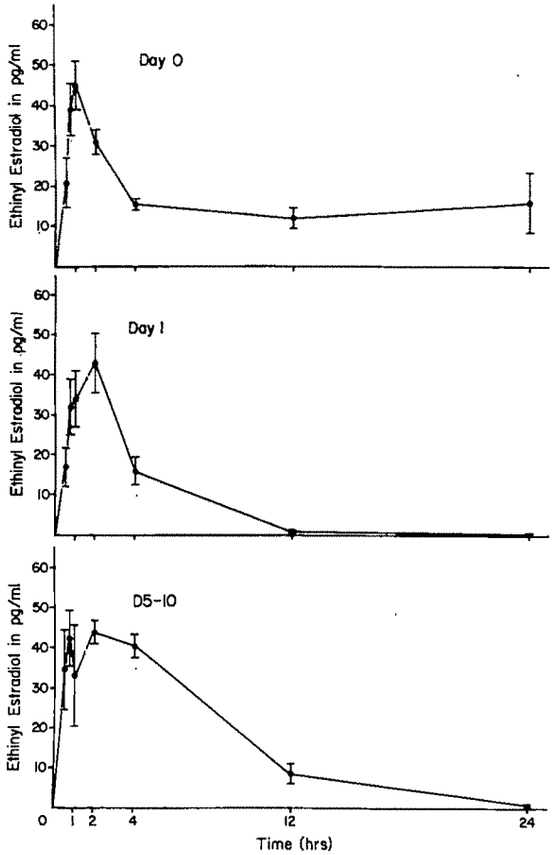

Fig. 1. Twenty-four-hour plasma levels of ethinyl estradiol on pill day 0 (oral contraceptive only) and on day 1 and days 5 to 10 after ingestion of tetracycline and oral contraceptive. Values are mean ± SEM.

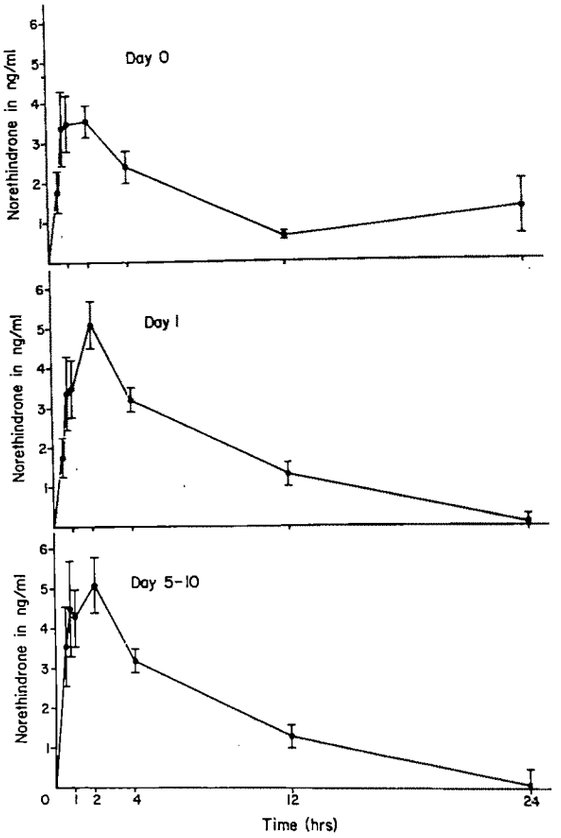

Fig. 2. Twenty-four-hour plasma levels of norethindrone on pill day 0 (oral contraceptive only) and on day 1 and days 5 to 10 after ingestion of tetracycline and oral contraceptive. Values are mean ± SEM.

The peak levels are reported as mean ± SEM. The subject who did not complete the study was included in the analysis.

Results

The mean (± SEM) 24-hour curves of ethinyl estradiol and norethindrone at day 0, day 1, and days 5 to 10 are shown in Figs. 1 and 2. The mean 24-hour area under the curve for ethinyl estradiol alone demonstrated no significant difference when compared with that for day 1 and days 5 to 10 (Table I). Similarly the mean peak value of ethinyl estradiol on day 0 was not significantly different from values on day 1 or days 5 to 10.

The mean 24-hour area under the curve for norethindrone demonstrated a statistically significant difference when day 0, day 1, and days 5 to 10 are compared ($p < 0.0007$) (Table I). Multiple range analysis by time revealed a significant increase between day 0–day 1 and days 5 to 10. The mean peak levels of norethindrone on day 0, day 1, and days 5 to 10 were significantly different ($p < 0.01$). Multiple range testing again revealed the increase to be between day 0–day 1 and days 5 to 10.

Four-hour area under the curve values for tetracycline in those subjects ingesting the oral contraceptive pill on day 1 and days 5 to 10 were not significantly different from those of subjects receiving tetracycline alone on day 1 or days 5 to 10 (Table II). Similarly, the peak levels of tetracycline did not differ from those of the oral contraceptive–tetracycline group on day 1 and day 5 or the tetracycline group on day 1 and days 5 to 10 (Table II).

Comment

The changes observed for 24-hour area under the curve for ethinyl estradiol and norethindrone demonstrate that oral contraceptive levels are not decreased by concomitant ingestion of tetracycline, either short-term (24 hours) or long-term (5 to 10 days). This is not

surprising since the only available data implicating tetracycline are from case reports that are uncontrolled, retrospective, and subject to recall bias.

The evidence cited for a potential clinically important broad-spectrum antibiotic and steroid interaction is based on several studies showing a reduction in urinary estriol excretion and lower serum estriol levels in pregnant women taking ampicillin.[9-12] This antibiotic is thought to alter the gastrointestinal metabolism of estrogens by decreasing the bacterial flora possessing glucuronidase and sulfatase enzymes, which are necessary for hydrolysis of conjugated steroids. This process is essential for reabsorption of estrogens because the conjugated steroids are poorly resorbed. The result is increased fecal loss of the conjugated steroids (estrogens and ethinyl estradiol in particular), thus reducing plasma levels of the steroid metabolites. This alteration in enterohepatic circulation is not relevant to the progestin component of oral contraceptives because only inactive progestin metabolites can be obtained after hydrolysis.[13]

The clinical importance of gastrointestinal metabolism of contraceptive steroids should be questioned.[14] The bioavailability of ethinyl estradiol and levonorgestrel does not appear to be reduced in women with an ileostomy.[15] Since the vast majority of glucuronidase activity in the human occurs in the large bowel, this study in women with ileostomy suggests that the enterohepatic recycling of contraceptive steroids may not be clinically significant in humans. Moreover, human studies do not suggest that contraceptive steroid levels are affected by treatment with ampicillin or metronidazole.[3, 16, 17] The ethinyl estradiol curve on day 0 does not suggest that the enterohepatic circulation is important in determining plasma levels of ethinyl estradiol. However, although we sampled over 24 hours, there are relatively few points on the curves between 4 and 24 hours. There may be secondary peaks, perhaps as a result of enterohepatic circulation, which we failed to detect.

Our data are the first to demonstrate that tetracycline does not decrease the peak plasma levels or the area under the curve for ethinyl estradiol. Our study included prospective follow-up of the subjects, therefore we were able to note the relatively large intersubject variability in plasma ethinyl estradiol levels with relatively small intrasubject variability. However, because of our study design (repeated measures analysis of variance), our ability to detect a statistical difference (power of the test) is much greater than with study designs that use unpaired groups. Failure to detect a difference is probably not a type II error; however, because of the relatively small number of subjects in the study, small differences would probably not be detected.

Our data demonstrate that norethindrone peak levels

and area under the curve did not decrease with either short-term (24 hours) or long-term (5 to 10 days) ingestion of tetracycline. Interestingly, both of the parameters evaluated showed a statistically significant increase between day 0–day 1 levels and levels on days 5 to 10.

Back et al.[18] report that the plasma half-life of the terminal, apparently monoexponential phase of norethindrone decay was between 6.1 and 12.3 hours in six subjects ingesting a single dose of 1 mg norethindrone and 50 μg ethinyl estradiol. During the long-term therapy with oral contraceptive pills, the plasma half-life did not differ. However, in four subjects receiving oral contraceptive pills for the first time, plasma concentrations of norethindrone rose progressively during the first cycle to concentrations higher than predicted from simple accumulation pharmacokinetics.[19] The sex-hormone-binding-globulin–binding capacity also increased, and there was a good correlation between the plasma concentration of norethindrone and the sex-hormone-binding-globulin–binding capacity. We have demonstrated a significant increase in sex-hormone-binding-globulin levels in patients ingesting a low-dose oral contraceptive containing 1 mg of norethindrone and 35 μg of ethinyl estradiol.[20] It is possible that levels of norethindrone may have been even higher with the oral contraceptive alone than with oral contraceptive pills and tetracycline on day 1 and days 5 to 10. These data are not available in our study. It is unlikely, however, that such is the case since a previous study with frequent, 24-hour sampling at 6 to 7 days of oral contraceptive (1 mg norethindrone, 30 mg ethinyl estradiol) use does not show an increase in norethindrone levels.

There is no evidence that the enterohepatic metabolism of progesterone or its metabolites is of any great physiologic importance in health or disease.[14] Moreover, although there are no data on the enterohepatic circulation of progestins in humans, it appears that in rats the bioavailability of progestins is not affected by changes in the enterohepatic circulation.[21] However, an effect of tetracycline on the enterohepatic circulation cannot be excluded.

The area under the 4-hour curve and peak levels of tetracycline do not appear to be decreased by oral contraceptives. Peak levels of tetracycline ranged from 5.1 to 7.9 μg/ml. In vitro studies indicate that concentrations above 2 to 4 μg/ml are therapeutic. Thus the results of our study suggest that the therapeutic efficacy of tetracycline is not reduced by the concurrent ingestion of a combination low-dose oral contraceptive. Similar results have been obtained with ampicillin and metronidazole.[3]

We have demonstrated for the first time that peak and 24-hour area under the curve for norethindrone and ethinyl estradiol do not appear to decrease in subjects ingesting tetracycline on either a short-term (24 hours) or a long-term (5 to 10 days) basis. While we have not examined pregnancy rates, unchanged or increased contraceptive steroid levels would suggest that the efficacy of the oral contraceptive is not reduced. Additionally, plasma levels of the antibiotic do not appear to be decreased in the presence of an oral contraceptive. Thus it would suggest that the therapeutic efficacy of tetracycline is not decreased.

We thank Janice Huth, Victoria Chang, and Joan Valentine for laboratory assistance, and Mr. Paul Shragg of the General Clinical Research Center for his statistical assistance.

Venous Doppler ultrasonography in the fetus with nonimmune hydrops

Saemundur Gudmundsson, MD, PhD,[a] James C. Huhta, MD,[a] Dennis C. Wood, RDMS, RCPT,[a] Gerald Tulzer, MD,[a] Arnold W. Cohen, MD,[b] and Stuart Weiner, MD[c]

Philadelphia, Pennsylvania

Eighteen pregnancies with nonimmune hydrops fetalis were referred for fetal echocardiography to rule out congenital heart disease. In 14 of these cases, pulsating blood velocities were recorded in the umbilical vein, which in a normal population had a nonpulsatile blood velocity pattern. The four cases without pulsations in the umbilical vein were found to have intrauterine viral infections. In the last 10 cases examined, the umbilical venous pulsations were found to reflect abnormal central venous pulsations during atrial systole suggesting increased fetal central venous pressure. Right ventricular shortening fraction was significantly decreased in the group with umbilical venous pulsations compared with those without (0.18 versus 0.32, $p < 0.05$). All the fetuses without venous pulsations survived, but only four of the 14 with pulsations survived ($p < 0.05$). The results suggest that blood velocity recordings in the umbilical and central veins of the fetus can give valuable clinical information with regard to the presence of fetal congestive heart failure and differentiate between this physiologic state and other causes of nonimmune hydrops fetalis. This may have implications for fetal diagnostic work-up and prognosis. (Am J Obstet Gynecol 1991;164:33-7.)

Key words: Fetus, nonimmune hydrops, Doppler ultrasonography, venous pulsations, congestive heart failure, umbilical vein

Nonimmune hydrops fetalis is a term applied to a fetus with excessive fluid accumulation in fetal body cavities along with soft tissue edema when fetomaternal blood group incompatibility is absent. Nonimmune hydrops fetalis has many causes,[1] but in many cases the common underlying pathophysiologic mechanism, whether primary or secondary, is heart failure.[2] In other cases of nonimmune hydrops fetalis, congestive heart failure may not be present. Noninvasive physiologic methods that define congestive heart failure in the fetus are not currently available but Doppler ultrasonography can provide blood velocity correlates of abnormal physiology. Umbilical venous pressure has been found to be increased in fetuses with congestive heart failure and hydrops from fetal anemia during cordocentesis[3] but there are no reliable noninvasive correlates of this hemodynamic state. Blood velocity fluctuations in the inferior vena cava have been reported as a correlate of central venous pressure changes in animal studies.[4]

While fetuses referred for echocardiography because of nonimmune hydrops fetalis were studied, abnormal blood velocity pulsations in the umbilical vein were noted. Our goals in this study were (1) to evaluate

whether the pulsating pattern could differentiate between cardiac and noncardiac involvement in nonimmune hydrops fetalis; (2) to investigate whether the abnormal pulsations were caused by atrioventricular valve insufficiency; and (3) to determine whether the venous blood velocity pattern could predict the fetal outcome of pregnancy.

Material and methods

Eighteen pregnant women with fetuses that had ultrasonographic evidence of nonimmune hydrops fetalis were referred for echocardiographic studies to rule out congenital heart disease. The mean age was 29 years (range, 19 to 38), five being nullipara, nine primipara, and four multipara. The mean gestational age was 29 weeks (range, 23 to 36). All the fetuses had fluid collections in two or more body compartments. Ascites was observed in all cases, 15 had pleural effusion, eight had pericardial effusion, and six had skin edema. Polyhydramnious was present in nine cases and oligohydramnious in one case. All fetuses had evaluation for fetal infection consisting of blood viral titers before or after delivery.

Six of the fetuses were the recipients in twin-to-twin transfusion as judged by discordant body size and only the hydropic twin in these pregnancies was analyzed. Four fetuses had supraventricular tachycardia and the assessment was performed during tachycardia. Five fetuses had viral infections documented by either positive immunoglobulin M titers (two with cytomegalovirus and one with parvovirus), and two with positive immunoglobulin G for cytomegalovirus and parvovirus, respectively. In another case the hydrops disappeared within 3 weeks, suggesting a viral cause. No cause of the hydrops was defined in three cases. Another fetus had a congenital heart malformation (a form of hypoplastic left heart syndrome with valvular regurgitation) and another had a placenta with multiple chorioangiomas.

A 3.5 MHz pulsed Doppler ultrasonogram in combination with a 3.5 MHz ultrasonographic sector scanner (Acuson 128) was used to record the umbilical artery blood flow velocity waveforms from a central portion of the umbilical cord. All recordings were performed without fetal breathing or body movements. The waveforms recorded were analyzed for pulsatility index according to Gosling et al.[5] and related to normal reference values.[6] Blood velocity was simultaneously recorded in the umbilical vein. All measurements were taken in the absence of fetal breathing. Normal umbilical vein blood velocity was affected by fetal breathing and abnormal venous pulsations are illustrated in Fig. 1. In the last 10 cases examined, blood velocities were also recorded from the fetal inferior vena cava between the entrance of the renal veins and the ductus venosus and the criteria of Reed et al.[11] were used to define significant reversal. All fetuses had 3.5 MHz color Doppler ultrasonography to locate the vessels and to search for atrioventricular insufficiency jets, which then were recorded by 3.5 MHz continuous-wave Doppler ultrasonography (Acuson 128). Doppler examinations were performed at least weekly in all patients before delivery but only the first examination at the time of diagnosis of hydrops was analyzed. The mean time interval between examination and delivery was 17 days (range, 0 to 62). The results of the fetal Doppler recordings were not available to the clinicians managing the patients. M-mode recordings were performed of the right ventricle in 16/18 fetuses and the shortening fraction was calculated as the diastolic minus the systolic dimension divided by the diastolic dimension.

Outcome was evaluated at review of newborn records for gestational age at delivery; birth weight[7]; delivery by cesarean section; intrauterine fetal death (death before or during birth); and neonatal death (up to 4 weeks after birth). Fisher's exact test (two-tailed) was used for statistical evaluation of the results. Parametric variables were compared with the unpaired two-tailed Student t test.

In addition, the umbilical vein velocity was recorded by the same method in 27 normal pregnant hospital staff volunteers after informed consent was obtained. A total of 51 examinations was performed between 20 and 40 weeks' gestation. All fetuses had a complete echocardiographic examination to exclude any evidence of congenital heart disease and a normal postnatal follow-up echocardiogram within the first 3 weeks after birth.

Results

Normal pregnancies. In our group of normal pregnancies, umbilical vein velocity was found to be even and without any fluctuations (except during fetal breathing movements) (Fig. 1) between 20 and 40 weeks' gestation. Whereas normal umbilical cord venous velocity is constant, fluctuating venous velocities were found to be normal in the peripheral veins such as the renal vein.

Nonimmune hydrops fetalis group. Eleven of the eighteen patients were delivered by cesarean section, two of which were indicated for fetal distress by fetal monitoring. The mean gestational age at delivery was 32 weeks (range, 23 to 41). The mean birth weight was 2022 gm (range, 560 to 4010).

Pulsating blood flow velocity in the umbilical vein was recorded in 14 of the 18 cases with nonimmune hydrops fetalis. In the four cases without pulsations in the umbilical vein, causes of the nonimmune hydrops fetalis were documented viral infections in three and viral infection was suspected in one. The fetal hydrops

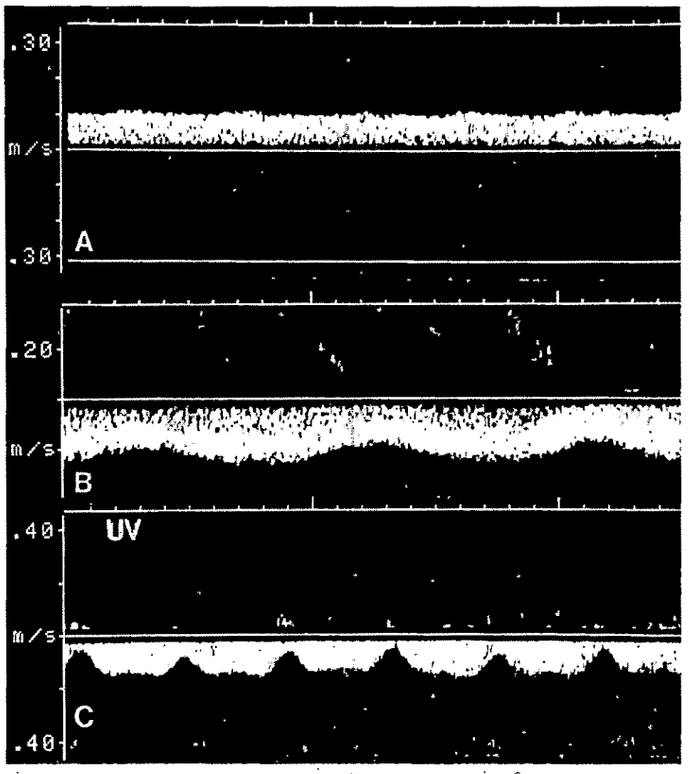

Fig. 1. Blood velocity in fetal umbilical vein. **A,** Normal blood velocity pattern; **B,** blood velocity influenced by fetal breathing; and **C,** venous pulsations in nonimmune hydrops.

resolved before delivery in these four cases; in one case fetal hydrops resolved after an intravenous fetal blood transfusion for anemia (parvovirus). The other three had mild hydrops that resolved within 21 days of diagnosis without treatment. Hydrops was present at delivery in 13 of the 14 cases with umbilical vein pulsations, but in none of the fetuses without umbilical vein pulsations. The one case in which umbilical vein pulsations were found before delivery and hydrops had disappeared by the time of delivery was a fetus that had supraventricular tachycardia that was successfully treated in utero. There was a significant difference in total mortality (10/14, 71%) between the group with venous pulsations and without (0.4, $p < 0.025$ (Table I). There were five intrauterine deaths that all had abnormal umbilical vein pulsations.

In 10 cases blood velocities were also recorded in the inferior vena cava and significant reversal was found in all with umbilical pulsations. The time velocity integral of the reversed flow in the inferior vena cava averaged 46% of the forward flow (range, 33% to 56%) compared with a normal maximum of 7% in our normal group. A normal and abnormal inferior vena cava blood velocity recording is illustrated in Fig. 2.

The umbilical artery blood velocity waveform pulsatility index was normal in all except two cases that had absent end-diastolic velocity. The mean pulsatility index ± SD values for both groups was not significantly different (Table I). The presence of valvular regurgi-

tation between fetuses with normal and abnormal umbilical venous blood velocities was not different although 8/14 had tricuspid regurgitation ($p < 1.22$). Right ventricular shortening fraction was significantly decreased in the group with umbilical venous pulsations compared with those without (0.18 versus 0.32, $p < 0.05$).

Comment

Doppler velocities in the umbilical artery give important physiologic information concerning the placental impedance and may aid in the management of high-risk pregnancies. However, umbilical venous Doppler velocities have not been used to evaluate fetal well being. In normal pregnancies we found that Doppler-recorded blood velocity in the umbilical vein is even and without fluctuation after 20 weeks' gestation. It is also our experience that the fetal inferior vena cava, renal, hepatic, axillary, and cerebral veins have pulsating blood velocities in normal pregnancy. Fourteen of the 18 fetuses with nonimmune hydrops fetalis in the present series had abnormal pulsations in the umbilical vein; the four fetuses without pulsations had proved or suspected viral causes. In the last ten cases examined, central venous blood velocities were also recorded and exaggerated fluctutations in velocities were present with reversal of flow away from the heart during end-diastole, which all exceeded the normal range.[8] Abnormal reversal of blood velocities in the central veins extended beyond the ductus venosus into the umbilical vein. These observations of an abnormal pressure wave during atrial systole point to cardiac involvement in the disease process. The finding of decreased ventricular shortening in those with pulsations suggests chronic congestive heart failure. Pulsations were not absolutely correlated with valvular regurgitation probably because the degree of myocardial dysfunction necessary to yield regurgitation depends on the cause of hydrops. Only one patient had hydrops because of a malformed valve. The importance of the finding of valvular regurgitation by Doppler ultrasonography in a hydropic fetus remains unclear. Nonetheless, venous pulsations were timed to atrial systole and were not correlated to valvular regurgitation.

An increase in capillary membrane permeability as a part of an inflammatory reaction might be the pathophysiologic mechanism behind the hydrops in the viral cases and gives hope that Doppler recordings of blood velocities in the central veins can distinguish between congestive heart failure and such a cause of nonimmune hydrops fetalis. A congenital infection may cause liver damage and hypoproteinemia as another possible mechanism for nonimmune hydrops fetalis, and myocarditis in such a fetus could result in congestive heart failure. Two of the fetuses in the group with viral infection (Table I) had pulsations in the umbilical vein;

both showed a decreased right ventricular shortening fraction and tricuspid regurgitation.

All the fetuses without pulsating blood velocities in the umbilical vein survived compared with only four of the 14 with abnormal pulsations. This might be explained partly by differences in gestational age at birth (Table I), but the hydrops had disappeared at delivery in all the cases without pulsations and in only one of the cases with pulsations—a case of supraventricular tachycardia that was successfully treated. The four caess with pulsations that survived had suspected viral causes of nonimmune hydrops fetalis (two) or supraventricular tachycardia (Table I). Absence of abnormal pulsations in the venous system, apart from being able to aid in the diagnosis of congestive heart failure with nonimmune hydrops fetalis, thus might also predict fetal outcome.

The umbilical artery blood velocity waveform was of limited value in the prediction of the fetal outcome of pregnancy. Two cases had absent end-diastolic blood velocities and all the others had normal umbilical artery pulsatility indexes even after correcting the values in cases with tachycardia according to Mires et al.[9] We speculate that umbilical artery flow velocity waveform does not reflect the disease state as in intrauterine growth retardation,[10] perhaps because significant elevations in placental or systemic vascular resistances are not necessarily a part of the pathogenesis of nonimmune hydrops fetalis.

Pulsating blood velocities in the umbilical vein have also been noted in human beings where this phenomenon was suggested as being a sign of a dysfunctional ductus venosus.[11] More likely, they reflect dynamic changes in venous flow similar to those in this group of patients. Reversal of end-diastolic blood flow in the fetal inferior vena cava has been reported to be associated with asphyxia in animal studies,[4] in human fetuses with α-thalasemic hydrops,[12] and in fetuses with arrhythmia or the absence of end-diastolic blood velocity in the umbilical artery.[8] The blood velocity waveform in the inferior vena cava was defined as abnormal when the time-velocity integral of the reversal of blood flow during atrial systole was >12% of the forward blood flow during one heart cycle. The reversal of blood velocities in the inferior vena cava in our series were all beyond this limit.

In conclusion, flow in the umbilical vein in normal pregnancies is constant in the absence of fetal breathing movements and pulsations in the umbilical vein are a reflection of central hemodynamics. Umbilical and central venous Doppler ultrasonography can give important information on the filling function of the heart and may be able to distinguish between fetuses with and without congestive heart failure that have nonimmune hydrops fetalis. Umbilical venous pulsations are not a direct result of tricuspid valve regurgitation but either sign appears to reflect cardiac involvement in nonimmune hydrops fetalis. The absence of pulsations in the umbilical vein may be a useful prognostic sign in the fetus with nonimmune hydrops fetalis.

The relationships among umbilical artery velocimetry, fetal biophysical profile, and placental inflammation in preterm premature rupture of the membranes

Alfred D. Fleming, MD, Carolyn M. Salafia, MD, Anthony M. Vintzileos, MD, John F. Rodis, MD, Winston A. Campbell, MD, and Kimberly F. Bantham, BS
Farmington, Connecticut

The relationships among umbilical artery velocimetry, fetal biophysical profile, and placental inflammation in 44 consecutive patients with preterm premature rupture of the membranes were determined. All patients were followed up with daily fetal biophysical profiles and systolic/diastolic ratios. After delivery, placental pathologic examination for histologic evidence of infection (umbilical vasculitis) was performed in all cases according to a standard protocol. The longitudinal trends of fetal biophysical profile scores and systolic/diastolic ratios were analyzed for patients with and without umbilical vasculitis. Analysis of the longitudinal trend during the period of 2 to 7 days before delivery showed that there were no differences of biophysical scores of systolic/diastolic ratios in either group. However, in the last examination, within 24 hours of delivery, patients with umbilical vasculitis had higher systolic/diastolic ratios and lower biophysical profile scores as compared with previous examinations. In addition, the biophysical profile score of the last examination 24 hours before delivery in patients with umbilical vasculitis was found to be significantly lower as compared with patients without umbilical vasculitis (mean ± SD, 6.6 ± 2.3 versus 8.2 ± 2.4, respectively). These data suggest that subclinical stages of infection are associated with biophysical alterations of the fetoplacental unit (i.e., simultaneous decrease in fetal biophysical activities and increase in systolic/diastolic ratios). Daily umbilical artery systolic/diastolic ratios, in conjunction with biophysical profiles, may be useful to follow up patients with preterm premature rupture of the membranes. (Am J Obstet Gynecol 1991;164:38-41.)

Key words: Umbilical artery velocimetry, fetal biophysical profile, placental inflammation, preterm premature rupture of the membranes

Acute intraamniotic infection is a major contributor to maternal and neonatal morbidity and mortality. This is because of the association of acute intraamniotic infection with preterm labor and maternal and neonatal sepsis. In our institution, patients with preterm premature rupture of the membranes (PROM) are followed up with daily fetal biophysical profiles. Patients in whom abnormal biophysical assessment develops are delivered promptly.[1] This approach is undertaken on the basis of our previous observations that suggested that abnormal biophysical assessment in patients with PROM precedes the development of overt clinical infection. In such patients, the fetal biophysical assessment is abnormal in the absence of fetal acidosis.[2] The cause of diminished fetal biophysical activities without blood acidosis has been related to the hemodynamic changes that accompany an increased production of prostaglandins from phospholipase A_2–producing bacteria. Because there are experimental data to suggest that prostaglandins increase placental vascular resistance through vasoconstriction of the umbilical and chorionic vessels,[3,4] it would be reasonable to investigate the role of umbilical arterial velocimetry in this group of patients.

The aims of the present prospective study were to test the hypothesis that the placental vascular resistance, as determined by umbilical artery velocimetry, is increased in patients with placental inflammation and to assess the relationships among umbilical artery velocimetry, fetal biophysical profile, and placental inflammation in patients with preterm PROM.

Material and methods

The study group consisted of 44 consecutive patients admitted with preterm PROM from July 1, 1988, to June 30, 1989. All patients were transported to the University of Connecticut Health Center from regional hospitals. All patients were middle to upper socioeco-

Group 1				
No inflammation (N = 17)	2.9 ± 0.24	2.7 ± 0.31	2.5 ± 0.45	2.6 ± 0.57
Group 2				
Umbilical vasculitis (N = 22)	2.8 ± 0.55	2.6 ± 0.40*	2.4 ± 0.32*	2.8 ± 0.55

Values are mean ± SD.
*p Value < 0.05 (as compared with the last examination 1 day before delivery).

nomic class. Of the 44 patients, 40 were white and four were black. Patients with clinical amnionitis or bleeding on admission were excluded. Patients were also excluded if other complicating factors such as pregnancy-induced hypertension, diabetes, or intrauterine growth retardation were present.

All patients had rupture of the membranes diagnosed by sterile speculum examination with pooled fluid, ferning, alkaline pH determination. Bimanual pelvic examinations were not performed unless the patient was in labor or induction of labor was planned. On admission to the hospital, maternal vital signs were recorded and electronic fetal heart rate monitoring was used to detect signs of fetal distress and document any uterine activity. In the absence of labor, fetal distress, or obvious clinical infection, ultrasonographic examination was performed to assess gestational age and to determine the fetal biophysical profile. The fetal biophysical profile was determined by a technique previously described.[5] The maximum score was 12 and the minimum 0. The ultrasonographic examination was performed by means of linear-array real-time ultrasonography (General Electric SRT 2600, Wilmington, Mass.) with a 3.5 MHz transducer. An abnormal biophysical assessment (score <7 on two examinations 2 hours apart in the presence of a nonreactive nonstress test and absence of fetal breathing) was used as an indication for delivery. Umbilical artery systolic/diastolic (S/D) ratios were also performed on admission by means of continuous-wave Doppler (Multigon 500A, Mt. Vernon, N.Y.). Three separate ratios were attained and the mean value recorded similar to the method described by Schulman et al.[6]

All patients were managed in the hospital with bed rest, bathroom privileges, daily biophysical profiles, and daily umbilical S/D ratios. The results of the umbilical artery velocimetry did not influence patient management. Temperatures were taken four times a day and white blood cell counts were performed daily. Increased white blood cell count alone was not used as an indication for delivery. Daily white blood counts were performed to aid in the diagnosis of clinical amnionitis; however, none of the patients had clinical infection during the antepartum period. Indications for delivery included abnormal biophysical profile, fetal distress on electronic fetal monitoring, or labor. Indications for cesarean section included history of previous cesarean section, fetal malpresentation, ominous heart rate pattern on internal fetal monitoring, and failure to progress. In patients with abnormal biophysical assessment, if the fetus was in vertex presentation and the fetal heart rate tracing reassuring (normal short-term variability by internal monitoring), induction of labor by oxytocin administration was undertaken.

Placental pathologic examination was performed in all patients according to standard protocol.[7] Placentas were weighed after removal of adherent blood clot and umbilical cord detachment. Two sections of umbilical cord, a section of membrane from the site of rupture, a membrane roll, and a section of chorionic plate with two chorionic vessels were examined from each patient.

Microscopic diagnoses were assigned by a single observer (C.M.S.) blinded to the biophysical scores and S/D ratio results.

In accordance with the placental pathologic findings, two groups were identified: group 1 had no histologic evidence of infection on maternal or fetal surfaces of the placenta; group 2 had histologic evidence of infection involving fetal polymorphonuclear leukocytes (umbilical, chorionic vasculitis). Patients with intermediate degrees of inflammation involving only maternal polymorphonuclear leukocytes (without umbilical-chorionic vasculitis) were also collected.

Statistical analysis of categoric variables (e.g., presence or absence of umbilical vasculitis) were performed with the use of contingency tables (Fischer's exact probability test). Analysis of continuous variables was performed by analysis of variance. Analysis of variance of repeated measures was used to check for significant daily changes between measurements (biophysical profile scores and S/D ratios). A p value <0.05 was considered statistically significant.

Results

The mean gestational age of the 44 fetuses was 29 weeks, with a range of 24 to 34 weeks. The cesarean section rate was 25/44 (57%). The indications for cesarean sections were repeat cesarean section (5 or 20%), fetal malpresentation (7 or 28%), nonreassuring fetal heart rate pattern on external monitoring with a closed cervix precluding internal monitoring (6 or 24%), ominous heart rate pattern on internal fetal monitoring (5 or 20%), and failure to progress (2 or 8%). Placental histologic examination resulted in the assignment of 17 patients to group 1 (no inflammation), and 22 to group 2 (umbilical vasculitis present). There were only five patients with placental inflammation confirmed only to the maternal surface (choriodeciduitis-chorionitis) and therefore they were excluded from further analysis. The mean gestational age of group 1 was 29.6 weeks (range, 24 to 33.5 weeks) and of group 2 was 29.0 weeks (range, 24 to 34 weeks). In group 1, delivery was indicated because of abnormal biophysical assessment in 4 of 17 (24%), labor in 11 of 17 (65%), and fetal distress in 2 of 17 (12%). In group 2 abnormal biophysical assessment was reported in 17 of 22 (77%) and labor in 5 of 22 (23%). The frequency of delivery for abnormal biophysical assessment was significantly higher in group 2 (77% vs 24%, $p < 0.05$).

The biophysical score and S/D ratio results according to placental infection outcome are shown in Tables I and II, respectively. During the period of 2 to 7 days before delivery, there were no differences between the two groups in terms of biophysical scores and S/D ratios. However, in the last examination within 24 hours of delivery, group 2 was found to have significantly lower biophysical scores as compared with group 1 (6.6 ± 2.3 vs 8.2 ± 2.4, respectively, $p < 0.05$). The longitudinal trend of the biophysical scores and S/D ratios results for each of the two groups revealed a significant decrease in the mean biophysical profile score of group 2 in the last examination within 24 hours before delivery, as compared with the previous examinations. Biophysical scores of patients in group 1 did not differ significantly from day to day including the last examination before delivery. In group 1 S/D ratios did not show significant differences in values observed on successive days before delivery.

In group 2 the mean S/D ratio of the last examination within 24 hours of delivery was significantly elevated as compared with previous examinations. The mean increase of S/D ratio values observed in the last examination before delivery in group 2 was 22% over previous examinations (range, 0% to 74%). An increase of >15% in S/D ratio would have a sensitivity of 63%, specificity of 73%, positive predictive value of 71%, and negative predictive value of 61% for prediction of acute umbilical vasculitis.

Comment

This study confirms the clinical association between abnormal biophysical profile assessment and histologic evidence of infection as determined by placental pathology. This study also suggests that the longitudinal trend in S/D ratio values may be an additional noninvasive means to identify fetuses at risk of ascending intrauterine infection with preterm PROM. The increase in S/D ratios observed longitudinally in fetuses from group 2 in the last 24 hours before delivery coincide with the decrease in biophysical score over the same time period. The increase in umbilical vascular resistance and diminished biophysical score supports a role for vasoactive substances (e.g., prostaglandins) as mediators of infection causing vasoconstriction of umbilical and chorionic vessels.[3, 4] This increase in vascular resistance may compromise uteroplacental circulation and diminish biophysical activities. Changes in fetal heart rate patterns have already been linked to the presence of histologic evidence of intraamniotic infection.[8, 9]

These observations further support the value of following up longitudinally the trends of both biophysical score and S/D ratio in patients with PROM. It might be that a decreasing trend in biophysical score and an increasing trend in S/D ratio values might increase the detection rate of fetuses at risk of infection. The fact that none of our patients had any clinical evidence of infection during the examinations suggests that the biophysical profile and S/D ratio become abnormal in subclinical stages of intraamniotic infection.

It should be emphasized that the mean S/D ratio in

the last examination within 24 hours before delivery in cases with umbilical vasculitis although elevated as compared with previous daily examinations is within normal limits according to previously established nomograms.[6] Other studies of the association of changes in S/D ratio with PROM have not described abnormal S/D ratios in this setting.[10] This is likely a result of two factors. First, the significant elevation of S/D ratio that was observed in the present study was only after follow-up of the longitudinal trend. Second, this elevation was confined to patients with placental infection. This emphasizes the importance of serial evaluation of S/D ratio in the setting of preterm PROM. Although umbilical cord gas values were obtained in all cases, no attempt was made in this study to correlate them with the biophysical assessment because we have previously shown that no such correlation exists in the presence of fetal infection.[2]

In summary, the present study provides pathologic evidence of the clinical association between abnormal biophysical assessment and impending infection in patients with preterm PROM. This study also suggests that umbilical artery velocimetry may have a role as a noninvasive means to follow up fetuses at risk of ascending intrauterine infection in patients with preterm PROM. Further studies are needed to determine whether the use of umbilical artery velocimetry can be an additional means to assess fetuses with preterm PROM to thereby reduce maternal and neonatal infectious morbidity and mortality.

Human immunodeficiency virus–induced immunosuppression: A risk factor for human papillomavirus infection

Roberto Matorras, MD, PhD,[a] Jose M. Ariceta, MD,[a] Angel Rementeria, MD,[a] Jesús Corral, MD,[b] Gloria Gutierrez de Terán, RN,[a] Javier Diez, MD,[a] Francisco Montoya, MD, PhD,[a] and Francisco J. Rodriguez-Escudero, MD, PhD[a]

Bilbao, Spain

In a group of 92 women with genital condylomata, 15 (16.3%) human immunodeficiency virus–positive patients were found, whereas no case was detected in a control group of 100 women. The relative risk was >19.28. Human immunodeficiency–positive status was associated with other parameters: lower age and parity, major frequency of induced abortions, and sexually transmitted diseases. Thus although human immunodeficiency–positive status seems to be a true risk factor in relation to the altered immunologic state, an indirect association cannot be discarded. Such patients should be screened closely for human papillomavirus infection and cervical cancer. Among human immunodeficiency–positive women, a more resistant behavior of human papillomavirus–associated lesions was detected (recurrence-persistence of 41.7% versus 12%), a fact that might also be in relation to the immunodepressed status. (AM J OBSTET GYNECOL 1991;164:42-4.)

Key words: Human immunodeficiency virus, acquired immunodeficiency syndrome, human papillomavirus, recurrence, persistence

Human papillomavirus (HPV) association with cervical cancer is well known. In HPV infection the immunologic status plays an important role. It has been reported that during states of altered immunity such as pregnancy[1] and in immunosuppressed patients there is an increased risk of HPV infection.[2] Interferon efficacy has been proved in the therapy of resistant condyloma.[3]

There are reports that the human immunodeficiency virus (HIV) infection might be associated with the HPV infection.[4] If this statement is confirmed, such patients should be screened closely for HPV infection, and therefore for cervical cancer.

Material and methods

Between 1986 and 1989 the diagnosis of HPV infection was established in 92 patients at the Colposcopy Unit of the Oncological Gynecology Service of the Hospital of Cruces, Pais Vasco University School of Medicine in Spain. The diagnosis was made on the basis of the presence of genitoperineal warts or a directed cervical biopsy specimen with evidence of HPV infection. The main epidemiologic features of this population have been reported recently.[5]

Papanicolaou smear, colposcopy, and colposcopically directed biopsies were performed in the usual way. Cytologic criteria for diagnosis of HPV infection were parakeratosis, koilocytosis and dyskaryosis. Colposcopic study was classified in three groups: (1) condylomatous (raised, irregular lesions); (2) atypical (abnormal lesions that were acetowhite and flat), and (3) normal (without colposcopic anomalies). Histologic features considered diagnostic of HPV infection were koilocytosis, dyskeratosis, multinucleation, and hyperkeratosis.

A randomized control group was established that comprised 100 women without pathologic findings who were attended in the same unit and whose macroscopic inspection, cervical cytology, and colposcopy showed no signs of HPV infection. In doubtful cases, directed biopsies were performed. Specific methods to detect HPV were not used in either the study group or in the control group.

In our Maternal Hospital the HIV antibodies detection test was performed during the same period in women with a history of intravenous drug abuse, prostitution, and partners of intravenous drug abusers or HIV-positive males. HIV antibodies were analyzed by means of enzyme-linked immunosorbent assay and confirmed by Western blot analysis and indirect immunofluorescence. HIV evolutive stage was studied by means of the determination of antigen p24 and antibodies anti-p24 by means of enzyme-linked immunosorbent assay.

Therapy consisted mainly of cryotherapy or laser therapy for cervical condylomata, whereas laser ther-

apy or local podophyllin were used in vulvoperineal lesions. There were no differences in the indications of different therapies among HIV-positive women and non-HIV–positive women.

The χ^2, Student *t* test, and Fisher exact test were used for the statistical analysis, following the standard criteria of applicability. The relative risk was determined by means of the odds ratio and its limits of confidence. When in one of the groups the number of cases was 0, the odds ratio was established considering 1 as the number of cases, and considering the odds ratio as more than the value determined this way.

Results

Prevalence. Among the 92 patients with condylomata, there were 15 HIV-positive women, representing 16.3% versus no HIV-positive case in the control group ($\chi^2 = 15.6$, $p < 0.001$, odds ratio >19.28, confidence limits >2.58 and >97.84). Among the 15 HIV-positive women there were 13 intravenous drug abusers, whereas in the remaining two patients the mechanism of acquisition was not known. In one patient there was evidence of acquired immunodeficiency syndrome and cerebral toxoplasmosis.

Personal history. Among condylomatous HIV-positive women the age and the number of deliveries were significantly lower than those in condylomatous non-HIV–positive women (Student *t* test = 2.88, $p < 0.01$ and Student *t* test = 2.46, $p < 0.05$, respectively) and those in the control group (Student *t* test = 11.18, $p < 0.001$ and Student *t* test = 8.71, $p < 0.001$, respectively). The age and the number of deliveries were also significantly lower in condylomatous non-HIV–positive women than those in the control group (Student *t* test = 3.40, $p < 0.001$ and Student *t* test = 6.69, $p < 0.001$), respectively.

Among condylomatous HIV-positive women the number of induced abortions was higher than in condylomatous non-HIV–positive women (Student *t* test = 2.88, $p < 0.05$) and the control group (Student *t* test = 2.83, $p < 0.05$). There were no differences between condylomatous non-HIV–positive women and the control group.

Condylomatous HIV-positive women and condylomatous non-HIV–positive women had a higher rate of sexually transmitted diseases than that in the control group (Fisher's exact test = 0.0001, $\chi^2 = 16.49$, $p < 0.001$). The differences between HIV-positive and non-HIV–positive condylomatous women with regard to sexually transmitted disease were close to the statistical significance limit (Fisher's exact test = 0.06).

Clinical findings. Ten of 15 HIV-positive women were first seen with vulvoperineal condylomata (66.7%). In 12 women cervical cytology gave evidence of HPV infection associated or not with different degrees of cervical intraepithelial neoplasia. There was grade 1 cervical intraepithelial neoplasia in two patients, grade 2 cervical intraepithelial neoplasia in three, and grade 3 cervical intraepithelial neoplasia in four, whereas in one patient condyloma was the only finding. In two patients cytologic study results were normal and in another patient such a study was not performed.

Colposcopy gave evidence of condyloma in five patients and results were atypical in seven (in one patient dysplasia-carcinoma was suspected). Colposcopic study found no anomalies in three patients.

Cervical biopsy. In 10 patients the cervix was studied histologically. The histologic diagnoses on the basis of the most severe change were condyloma without atypia in three patients, and in five patients condyloma with different degrees of cervical intraepithelial neoplasia (one grade 1, three grade 2, and one grade 3). In two women, cervical biopsy specimens were normal.

Evolution. Sixty-two patients were followed up for ≥6 months. Among the 12 HIV-positive women, there was persistence or recurrence of HPV-associated lesions in five (41.7%) versus six of the 50 non-HIV–positive women (12%) ($p = 0.03$, Fisher's exact test). Seven HIV-positive women were serologically followed up. One of them was the woman with acquired immunodeficiency syndrome and cerebral toxoplasmosis. In two other patients decreasing antibody levels (anti-

p24) and increasing p24 antigen levels were detected. The remaining four patients were antibody-positive and antigen-negative.

Comment

There are several facts that relate HPV infection to the immunologic status, such as the increased risk in immunodepressed patients[2] and the major frequency[1] and rapid growth during pregnancy,[6] as well as interferon efficacy in the therapy of resistant condyloma.[3] However, only recently an association between HPV- and HIV-induced immunosuppression has been reported. Henry et al.[4] described four HIV-positive women with HPV infection and different degrees of cervical intraepithelial neoplasia.

In our experience 15 HIV-positive women (13 of them heroin addicts) were found to have a clinically detectable HPV infection either in the vulvoperineal area, the cervix, or both. It must be kept in mind that HIV-positive women were significantly younger, with fewer children, and with more induced abortions than those of the control group and those of women with condylomata but who are non-HIV–positive. Sexually transmitted diseases were also significantly increased versus the control group and levels were close to the statistical significance limit versus condylomatous non-HIV–positive women. Thus in our series it was not possible to determine whether the HIV-positive status was a true risk factor or an indirect association. In our study, clinically undetectable HPV infection was not analyzed in the control group. Thus it cannot be discarded that the HIV-positive status could promote the clinical manifestation of latent infections.

Anyway, among HIV-positive women the prevalence of HPV-associated lesions was markedly increased (relative risk, >19.28), justifying a close screening for HPV and cervical cancer in these patients. In our opinion any patient who is an intravenous drug abuser with an HPV infection should have an HIV test, as well as patients with histories of multiple persistence or recurrence of HPV-associated lesions after therapies.

On the other hand, the more resistant behavior of HPV-associated lesions among HIV-positive women could also be in relation to the immunodepressed status. In accordance with this, Carson et al.[2] suggested that patients with multiple recurrent condylomas and genital neoplasias may have underlying immunodeficiency. More data are needed to determine the value of interferon in such patients and to state whether the increased resistance to therapy causes an increased oncogenic transformation.

Endometriosis associated with massive ascites and absence of pelvic peritoneum

R. Stan Williams, MD, and Rebecca Wagaman, MD
Gainesville, Florida

Although massive ascites associated with endometriosis has been reported in rare cases, this patient was also noted to have massive destruction of the pelvic peritoneum. Failure of medical suppression necessitated total abdominal hysterectomy and bilateral salpingo-oophorectomy. Several months after surgery ascites resolved, possibly with reestablishment of the pelvic peritoneum. (AM J OBSTET GYNECOL 1991;164:45-6.)

Key words: Endometriosis, ascites, peritoneum

Massive ascites associated with endometriosis is rare, having been described in fewer than 20 patients in the English literature.[1] This is a case report of a patient who presented with massive ascites associated with endometriosis; she was also found to have complete destruction of the overlying pelvic peritoneum.

Case report

A 27-year-old black woman, para 0, presented to the Shands Emergency Room at the University of Florida complaining of increasing abdominal girth and shortness of breath for the past 3 months. Endometriosis had been diagnosed by laparoscopy at another hospital 2 years before this presentation. At that time she had complaints of pelvic pain, dysmenorrhea, and dyspareunia. She was treated with a 9-month course of Danocrine postoperatively and her pain resolved with this therapy. She underwent a repeat laparoscopy after completion of Danocrine therapy because of persistent palpable pelvic endometriosis. Endometriosis was again confirmed. Postoperatively, the patient developed a large incarcerated left diaphragmatic hernia and underwent a left thoracotomy. Pathologic examination of the excised diaphragmatic tissue confirmed focal endometriosis with fibrosis. The patient did well until approximately 4 months after surgery when she began to complain of rapidly increasing abdominal girth and subsequent development of a ventral incisional hernia.

6/1/24396

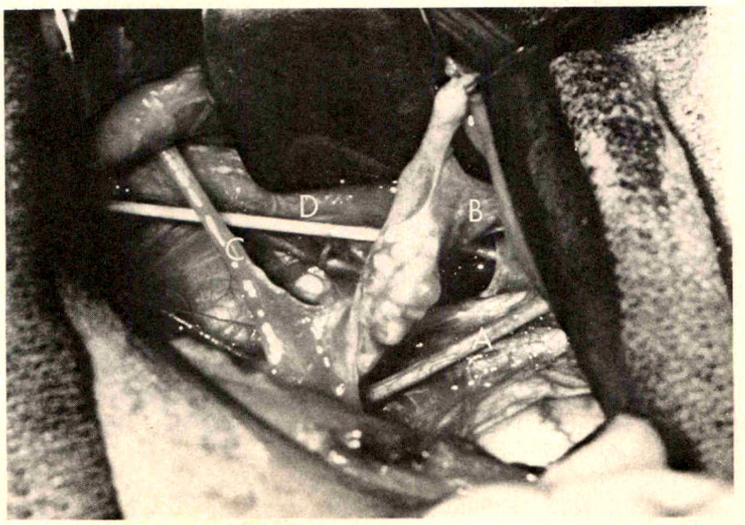

Fig. 1. At laparotomy complete absence of pelvic peritoneum and adventitia was noted with ureters, vessels, and nerves exposed. *A*, Ureter. *B*, Infundibulopelvic vessels. *C*, Round ligament. *D*, Obturator nerve.

She underwent repair of the ventral hernia, at which time a large amount of ascitic fluid was drained.

Evaluation of her massive ascites included negative bacterial and fungal cultures, and normal results of cytologic tests, computerized tomographic scan, complete blood count, electrolyte levels, liver function tests, renal function tests, serum albumin levels, and total protein level. In light of the previous diagnosis of endometriosis, it was thought that ascites was secondary to endometriosis. The patient was begun on a regimen of suppressive therapy with medroxyprogesterone acetate. After 1 month of therapy, the ascites failed to resolve further. She was then treated with depot Lupron (TAP Pharmaceuticals, North Chicago) injection and over 3 months lost an additional 10 pounds of fluid, but she still had a significant amount of ascites. The patient requested definitive surgery.

At the time of laparotomy for total abdominal hysterectomy and bilateral salpingo-oophorectomy she had complete absence of the pelvic parietal peritoneum (Fig. 1). Seven and one-half liters of ascitic fluid was drained. The ureters, blood vessels, and nerves coursed along the pelvic sidewall completely unenveloped by peritoneum or adventitia. The only evidence of gross endometriosis at this time was some scarring in the posterior cul-de-sac overlying the sigmoid colon. Pathologic evaluation confirmed endometriosis in the uterine serosa. One month after operation, there was no evidence of reaccumulation of ascites. Over the next 3 months the patient experienced reaccumulation of ascites and underwent a repeat ventral hernia repair, at which time a Tenchoff catheter was placed. After drainage for 2 weeks, the Tenchoff catheter was removed. Over the past 9 months, there has been no evidence of reaccumulation of ascites.

Comment

This report represents not only the rare association of endometriosis and massive ascites but, in addition, a new finding of complete disappearance of the pelvic peritoneum in association with endometriosis and massive ascites. Although it is recognized that small circular peritoneal defects can be associated with endometriosis,[2] this is the first report of the massive destruction of the entire pelvic peritoneum by endometriosis. Although this patient has not undergone subsequent laparotomy or laparoscopy since the ascites has resolved, it is possible that with the resolution of endometriosis, the normal intraperitoneal mechanisms for healing peritoneum have resulted in the reperitonealization of the pelvis.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Obstetrics & Gynecology®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Editors: Daniel R. Mishell, Jr., M.D.; Thomas H. Kirschbaum, M.D.; and C. Paul Morrow, M.D. **Contributing Editor**: William H. Hindle, M.D.

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

IN POSTPARTUM ENDOMETRITIS*

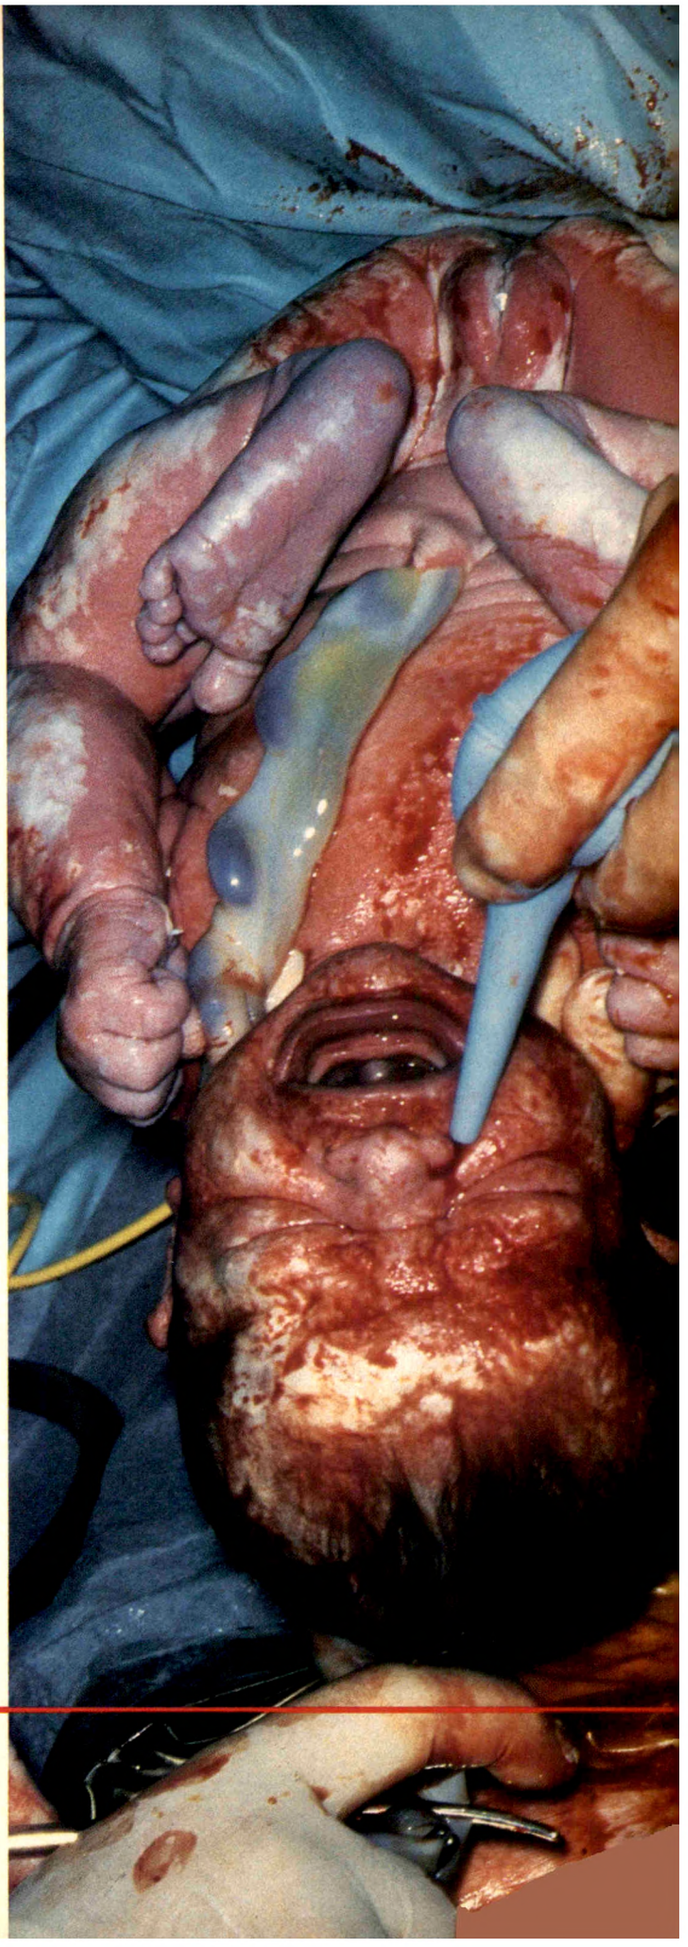
A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

Azactam®
aztreonam
delivers...

**Due to susceptible organisms.*

[1]Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.



[‡]Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.†*
- *Greater than 90% cure rates in combination with clindamycin.[1-3]*
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.‡*
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

Azactam®
aztreonam

A logical alternative to aminoglycosides.

Please see adjacent page for brief summary of prescribing information.

Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae*,* and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

Endometrial thickness as measured by endovaginal ultrasonography for identifying endometrial abnormality

Seth Granberg, MD, Mats Wikland, MD, Bengt Karlsson, MD, Anders Norström, MD, and Lars-Gösta Friberg, MD

Göteborg, Sweden

Diagnostic curettage has for many years been the method of choice to diagnose endometrial cancer in women with postmenopausal bleeding. The costs for curettage performed today are huge, and approximately only 10% in this group of women will be diagnosed with endometrial cancer. Thus less expansive techniques to obtain endometrial samples have been evaluated, but all of them are invasive. The value of endovaginal ultrasonography for identifying endometrial abnormality in this group of women has not been evaluated until now. This study used endometrial thickness as measured by endovaginal ultrasonography as an indicator of endometrial abnormality. It was demonstrated in 205 women with postmenopausal bleeding that if the endometrium was <9 mm thick, no endometrial cancer was found at curettage. The mean endometrial thickness in those women with endometrial cancer was 18.2 ± 6.2 mm as compared with 3.4 ± 1.2 mm in those women with atrophic endometrium. If the cutoff limit for endometrial abnormality was 5 mm, the positive predictive value for identifying endometrial abnormality was 87.3%. If this limit had been used in this study, 70% of the curettage procedures could have been avoided. (AM J OBSTET GYNECOL 1991;164:47-52.)

Key words: Endometrium, endovaginal ultrasonography, endometrial cancer

Postmenopausal bleeding has always been an absolute indication for curettage. Curettage was introduced as early as 1843 by Recamier but came to be a diagnostic procedure in the 20th century. The technique carries a small but real risk of morbidity and death.[1] Furthermore, curettage causes a great deal of anxiety to the patient. With the knowledge that almost 70% of diagnostic curettages result in a diagnosis of a benign condition, an improved "preoperative" evaluation could reduce the number of curettages and bring down the costs considerably.[2, 3] Many different methods have been developed to minimize the need for curettage.[1, 2] One such method is Vabra aspiration (Milex Products, Inc., Chicago). Compared with curettage, it is more convenient since there is no need for general anesthesia, thereby minimizing the risk to women.[1] However, the diagnostic accuracy, when compared with that of curettage, has been debated.[4] This is one reason the use of these methods so far has not significantly influenced the number of curettages performed in women with postmenopausal bleeding.

The histopathologic diagnosis obtained at curettage is used as the gold standard for distinguishing between benign and malignant endometrium. However, the false-negative rate is 2% to 6%.[1, 4-6] This is probably due to the fact that curettage is no guarantee that the uterine cavity has been sufficiently emptied.[6] Thus it is not surprising that some studies have found almost 6% of cases of hyperplasia and cancer were missed at curettage performed before hysterectomy.[4]

Diagnostic ultrasonography is a very good instrument for evaluation of endometrial growth in menstruating women.[7, 8] It is well known that the phasic variation in endometrial thickness can be easily visualized by ultrasonography.[7, 8] However, our knowledge of endometrial thickness as measured by ultrasonography in postmenopausal women is limited.[9, 10] So far, ultrasonography has been mainly used for evaluation of myometrial infiltration[11-15] in women with known endometrial cancer.

With the introduction of vaginal ultrasonography, ultrasonographic examination of the uterus in postmenopausal women has become very easy and quick. However, to the best of our knowledge, endovaginal ultrasonography has not been used for evaluation of endometrium in women with postmenopausal bleeding. This study was done to find out if there is any relation between endometrial thickness as measured by

vaginal ultrasonography and pathoanatomic diagnosis of the endometrium obtained at curettage in women with postmenopausal bleeding.

Material and methods

Two hundred five women with postmenopausal bleeding who were admitted to the hospital for curettage, were scanned endovaginally the day before operation. The ultrasonographic examinations were performed by use of a Brüel & Kjaer ultrasonography machine (model 1846) equipped with a vaginal transducer (model 1836) (Brüel & Kjaer, Naerum, Denmark). This mechanical transducer has a scanning sector of 112 degrees and a frequency of 7 MHz. The focal range of the transducer is 6 cm from its tip.

Before ultrasonographic examination, the patient emptied the urinary bladder. The examination was performed with the patient in lithotomy position. The transducer was introduced into the posterior vaginal fornix, and the uterus was scanned longitudinally and transversely. Endometrial thickness was measured at the thickest part in the longitudinal plane (Fig. 1). The measurement included both endometrial layers; that is, the measurement was performed between the two basal layers of the anterior and posterior uterine wall, also including the distended uterine cavity (Fig. 1). The poorly reflective layer surrounding the highly reflective endometrium was not included in the measurement, which was obtained by means of the electronic caliper built in the ultrasonography machine. All structures in the lower pelvis and urinary bladder that were considered abnormal by ultrasonography were noted. A curettage was performed by experienced gynecologists in the department.

The histopathologic diagnosis was used as the gold standard. In 11 patients the endometrial tissue obtained was insufficient for histologic diagnosis despite the fact that the surgeon stated that he or she had curetted the uterine cavity meticulously. According to principles used in our department, such an endometrium is classified as atrophic and benign even if it has not been possible to obtain a histologic diagnosis. For this reason these 11 patients were included in the study, and the endometrium was classified as atrophic and benign.

Within 2 weeks after curettage 15 patients were operated on because of a pelvic tumor found at ultrasonographic scanning before curettage. In all of these women hysterectomy and bilateral salpingo-oophorectomy were performed. Estrogen therapy

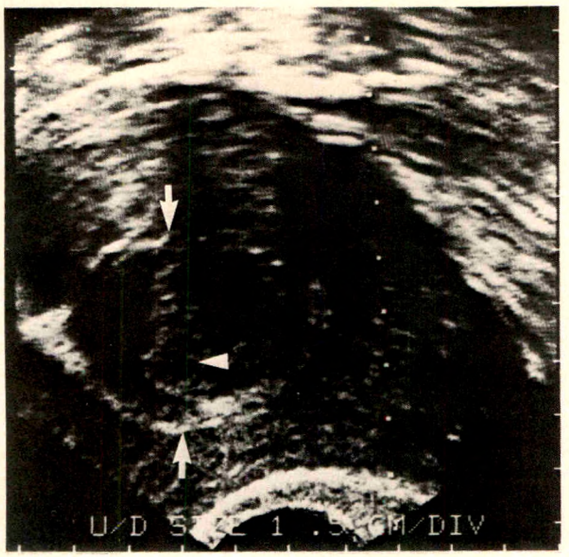

Fig. 3. Endometrial polyps *(white arrowhead)* as imaged by endovaginal scanning. *White arrows* indicate distended endometrial cavity. Orientation as in Fig. 1. *Size:* 1.5 cm between *vertical lines* at bottom of figure.

among the admitted patients was noted. Two groups of women were included as references. One group comprised 30 postmenopausal women without any vaginal bleeding admitted for surgical treatment of urine incontinence or prolapse. The other group comprised 30 women with previously diagnosed endometrial cancer. These 30 women underwent scanning 4 weeks after curettage, at which time the diagnosis was made but intracavitary radiation therapy had not been started. Five postmenopausal patients with vaginal bleeding were not included in the study since the initial gynecologic examination revealed a macroscopically visible tumor of the cervix.

Results

In 30 postmenopausal patients without vaginal bleeding, mean endometrial thickness was 3.2 ± 0.7 mm whereas the corresponding value for patients with known endometrial carcinoma was 17.7 ± 5.8 mm (Table I). Atrophic endometrium was found in 157 women (78%) (Fig. 2), endometrial polyps in 13 women (Fig. 3), endometrial hyperplasia in 13 (Fig. 4), and endometrial carcinoma in 8 women (9%) (Fig. 5) (Table II). Pyometra was found in three women, and one woman had hematometra (see Table II, "others"). In women with a histopathologic diagnosis of atrophic endometrium, mean endometrial thickness was 3.4 ± 1.2 mm (Table II). In women who had endometrial cancer, mean endometrial thickness as measured by vaginal

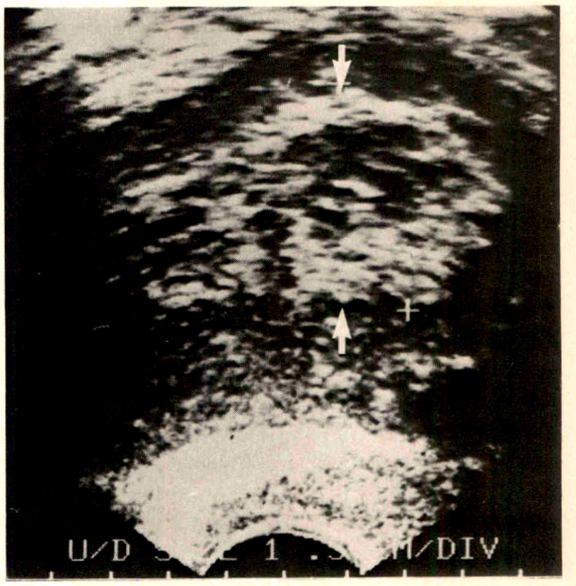

Fig. 5. Endometrial cancer as imaged by endovaginal ultrasonography. Note thick (between *white arrows*) and irregular outlining of endometrium. Orientation and size as in Fig. 3.

ultrasonography was 18.2 ± 6.2 mm (Table II). No endometrial cancer was found in endometrium that had a thickness of ≤8 mm. All endometrial carcinomas were found in patients with endometrial thickness of ≥9 mm (Table III).

Figures indicate number of women.

In all 30 patients who had been on a regimen of estrogen therapy at the time of postmenopausal bleeding, histologic diagnosis was atrophic (benign) endometrium. Five (17%) of these women had endometrial thickness of >5 mm (Table IV). Of those 127 women with benign histologic results who had not been receiving estrogen therapy, only two had endometrial thickness of >5 mm (Table IV). In this group of women the thickest endometrium was 7 mm, as compared with 11 mm in the group of women who had been on a regimen of estrogen therapy.

In 24 (11%) of the 205 women examined the ultrasonographic examination indicated the existence of other pelvic pathologic conditions that required further investigation. Final diagnosis in those women is shown in Table V. Fifteen of the 19 women who underwent laparotomy eventually underwent hysterectomy and bilateral salpingo-oophorectomy. In all but one woman the diagnosis obtained at curettage agreed with the histologic diagnosis of the endometrium obtained after surgery. This woman had an endometrial thickness of 9 mm but D & C revealed atrophy. The final diagnosis after laparotomy was a granulosa cell tumor and hyperplasia of the endometrium.

Comment

The diagnostic accuracy of curettage as compared with more simple procedures such as Vabra aspiration has been questioned.[1, 4] It has been shown by Stock and Kanbour[5] that in approximately 60% of the curettage procedures less than half of the uterine cavity is curetted. It must also be kept in mind that the overall costs for the vast number of curettages being performed are tremendous.[4] Furthermore, these elderly women have a small but real risk of morbidity and death.[4] With this in mind and the knowledge that only approximately 10% of women with postmenopausal bleeding have endometrial carcinoma, there is still a need to evaluate simpler, less expensive, and safer diagnostic methods that can exclude endometrial pathologic conditions. One such method is Vabra aspiration, which has been evaluated in several studies.[1, 4] Ultrasonography is another, fairly simple method that has been used for studying the endometrium.[7-9, 16] With high-frequency vaginal ultrasonography the endometrium can easily be visualized. Ultrasonography also has been used for studying endometrial carcinoma, but it has been difficult to find any specific echo that is characteristic of endometrial carcinoma.[11-15] On the other hand, ultrasonography has been shown to be a valuable instrument for staging known endometrial carcinoma.[11-15]

There are very few studies, however, where ultrasonography has been used for evaluation of endometrium in women with postmenopausal bleeding.[17, 18] Earlier studies within this field have used abdominal ultrasonography. Vaginal ultrasonography is a rather new technique that has not been extensively evaluated with regard to its use for early identification of endometrial abnormality in postmenopausal women.

The purpose of this study was to evaluate endome-

trial thickness as measured by vaginal ultrasonography as the only parameter for excluding endometrial abnormality. The mean endometrial thickness of 3.2 mm in postmenopausal women without any vaginal bleeding is similar to what has been found by other investigators by endovaginal ultrasonography.[17, 18] This figure is very similar to that (3.4 mm) found in women with vaginal bleeding but without any endometrial pathologic conditions as shown by curettage. In this study no endometrial abnormality was found if the endometrium was <6 mm thick. This is in agreement with Nasari and Coast,[17] as well as Fleischer et al.,[18] although they had fewer patients in their studies. It seems reasonable to have a cutoff limit for normal, "benign" postmenopausal endometrium at 5 mm (including both layers). In this study no endometrial cancer was found with endometrial thickness <9 mm, and mean endometrial thickness in those with endometrial carcinoma was 17.7 mm, which was almost the same as that for the 30 patients with previously diagnosed carcinoma of the endometrium (18.2 mm). The difference between thickness of atrophic endometrium, as measured by vaginal ultrasonography, and thickness of endometrium with carcinoma indicates that ultrasonography could be used as a very simple method to exclude endometrial carcinoma as the cause of postmenopausal bleeding. With regard to endometrial abnormality no false-negative observation was obtained if a 5 mm cutoff limit was used for endometrial thickness. This means a positive predictive value of 87.3%, a specificity of 96%, and a sensitivity of 100% for identifying endometrial abnormality with the presented technique. The corresponding figures for a cutoff limit of 4 mm were 60.8%, 80.2%, and 100%.

If these results hold true in the future, a vaginal ultrasonographic examination showing an endometrial thickness of <5 mm in a woman with postmenopausal bleeding could then mean that curettage could be avoided. It has been shown that approximately 80% of all curettages performed because of postmenopausal bleeding result in a benign diagnosis.[1, 3, 4, 6, 9] In this study 70% of curettages performed could have been avoided if the 5 mm limit had been used. Since a curettage is one of the most frequently performed gynecologic operations, a reduction of these by 50% would result in considerable savings[1, 4] with regard to both potential risks of the operation and economic costs.

It is interesting that endovaginal ultrasonographic examination in the 205 women with postmenopausal bleeding revealed other pelvic abnormality that would probably not have been diagnosed that early if the ultrasonographic examination had not been performed (Table V). It was unexpected to find five urinary bladder tumors. Of course it is not surprising that bleeding from the bladder can be mistaken for vaginal bleeding by the patient. The number of bladder tumors (5/205) is, however, probably too high since Benacerraf et al.[19] reported only three bladder tumors among 3000 gynecologic ultrasonographic examinations. The incidence of urinary bladder tumors in the age group 50 to 70 years is reported to be 28 per 100,000, which is much less than our figures would indicate.[20] However, one must remember that we have been studying a group of women with specific symptoms.

To evaluate the exact diagnostic accuracy of vaginal ultrasonography for excluding endometrial abnormaltiy, as well as other pelvic abnormality, as the cause of postmenopausal bleeding, one should include about 2000 to 3000 women in the study. To accomplish such an investigation within a reasonable time period, a multicenter study has been started in the Nordic countries. If the results presented here hold true, the number of curettages could be remarkably reduced, thereby benefiting the patients and saving money for the community.

Table IV. Endometrial thickness as measured by vaginal ultrasonography in women with and without estrogen therapy and a benign histologic diagnosis

The use of the Cytobrush cervical sampler in patients with cervical stenosis

Mitchel S. Hoffman, MD, Lorraine W. Gordy, CT, and Denis Cavanagh, MD
Tampa, Florida

In 37 of 43 patients (86%) with cervical stenosis (inability to undergo passage of the cotton-tipped applicator), the Cytobrush cervical sampler was successfully passed into the endocervical canal. The use of the Cytobrush sampler for cervical cytologic screening appears to be valuable in patients with cervical stenosis. (Am J Obstet Gynecol 1991;164:52-3.)

Key words: Cytology, cervical stenosis

The presence of endocervical cells is generally recognized as an important criterion for consideration of a cervical cytologic sample as adequate.[1] A variety of methods have been devised to improve endocervical cytologic sampling.[2] Several recent studies have suggested superior endocervical cell yield with the use of an endocervical brush (Cytobrush; M-Medscan AB, Malmo, Sweden; marketed in the United States by International Cytobrush, Inc., Hollywood, Fla.).[2] The present study was undertaken to evaluate the value of the Cytobrush sampler in patients with cervical stenosis.

Material and methods

Between Aug. 1, 1987, and Jan. 31, 1990, a separate "standard" Papanicolaou smear and an endocervical brush smear were obtained from each of the 491 consecutive patients entered into the study at the Tampa General Hospital and the H. Lee Moffitt Cancer Center and Research Institute colposcopy clinics. An analysis of the entire 491 patients will be the subject of another report.

From the Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, University of South Florida College of Medicine at H. Lee Moffitt Cancer Center and Research Institute and Tampa General Hospital.
Received for publication March 27, 1990; revised July 25, 1990; accepted August 7, 1990.

6/1/24449

The first smear was obtained by using an Ayres spatula followed by a moistened cotton-tipped applicator in the endocervical canal. The moistened cotton-tipped applicator was inserted into the endocervical canal and rotated for 5 to 10 complete turns with slight pressure against the walls of the canal; an attempt was made to sample the entire endocervical canal. The material was immediately fixed on a standard glass slide with cytofixative. Immediately after this, a separate smear was obtained with the Cytobrush sampler by means of the same procedure that was used with the cotton-tipped applicator. Cervical stenosis was defined in this study as inability to introduce the moistened cotton-tipped applicator beyond the external os. In the event of cervical stenosis passage of the Cytobrush sampler into the endocervical canal was still attempted. Both smears were reviewed by cytotechnologists for the presence of endocervical cells. Patient data and results were collected prospectively during accrual. Patients were excluded from the study in the event of pregnancy or prior pelvic radiotherapy.

Results

Of the 491 total patients, 43 (7%) were identified as having cervical stenosis. The mean age of the entire patient population was 31 years (range 13 to 89 years). The mean age of the 43 patients was 42 years (range 26 to 89 years). Eighteen of the 43 patients were postmenopausal and 12 of the 43 patients had undergone prior cryotherapy. Two of the patients had undergone a laser conization of the cervix and two patients had undergone prior cold knife conization of the cervix. In 13 of the 43 patients (30%) endocervical cells were found on the "standard" Papanicolaou smear. In 38 patients (88%) the Cytobrush sampler was successfully passed into the endocervical canal. In one of these 38 patients the cytobrush specimen contained no endocervical cells, so that a total of 37 out of the 43 Cytobrush sampler specimens (86%) contained endocervical cells. With the χ^2 method for statistical comparison, the difference in endocervical cell yield between the "standard" Papanicolaou smear and the Cytobrush sampler was significantly different ($p < 0.01$).

Comment

As previously stated, the presence of endocervical cells is generally thought to be important for adequate cervical cytologic screening. Adequate sampling of the endocervical canal may be especially important in patients with cervical stenosis. The transformation zone in these patients is frequently within the endocervical canal, and in addition many of these patients have a history of treatment for precancerous lesions of the cervix. The very low endocervical cell yield (30%) by the "standard" Papanicolaou smear in patients with cervical stenosis in this study suggests that the standard Papanicolaou smear obtained with an Ayres spatula and a moistened cotton-tipped applicator is inadequate in these patients. We conclude from this study that the Cytobrush sampler is of value for obtaining an adequate cervical cytologic specimen in patients with cervical stenosis.

Low level of maternal serum α-fetoprotein: Its associated anxiety and the effects of genetic counseling

Kathy L. Keenan, MS, Deborah Basso, MD, John Goldkrand, MD, and William J. Butler, MD

Albany, New York

A low maternal serum α-fetoprotein screening result can be expected to cause measurable anxiety for couples, particularly when the woman is younger than 35 years of age. This study was designed to investigate the levels of anxiety present in these patients and show the effectiveness of genetic counseling on this anxiety. The women and their partners were given the State Trait Anxiety Inventory before and after counseling. A control group of low-risk pregnant patients was also given the state anxiety inventory for comparison. The mean level of anxiety for the control group was 36, significantly lower than either the precounseling or postcounseling level of the group with low maternal serum α-fetoprotein screening results ($p < 0.05$). The study shows that genetic counseling, in addition to apprising couples of the risks and options involved, does significantly reduce their anxiety level regardless of whether an amniocentesis was performed. (AM J OBSTET GYNECOL 1991;164:54-6.)

Key words: Anxiety, low maternal serum α-fetoprotein, genetic counseling

As the national perinatal mortality rates progressively fall, congenital malformations and chromosomal abnormalities make an even larger contribution to fetal death and long-term disability. Chromosomal problems, principally Down syndrome, remain the leading cause of mental retardation. Despite the use of prenatal diagnosis, the estimated crude incidence of Down syndrome in the United States remains stable at 1 per 1000 births.[1] As the percentage of trisomy 21 births attributed to women over the age of 35 years declines, the number of Down syndrome births to women under the age of 35 reaches as high as 75% to 80%.[1]

In 1984, Merkatz et al.[1] reported that maternal serum α-fetoprotein levels were about 25% lower, on the average, in Down syndrome pregnancies than in unaffected pregnancies. This association has been repeatedly confirmed.[2, 3] Subsequently, Cuckle et al.[4] suggested that measurement of maternal serum α-fetoprotein might serve as a screening test for Down syndrome, even though a considerable overlap existed between the curves for affected and unaffected pregnancies. With maternal age of 35 years as the lone criterion for offering prenatal diagnosis, approximately 20% of all Down syndrome cases would be detected. The finding that low levels of maternal serum α-fetoprotein were associated with Down syndrome pregnancies meant that now it would be possible to justify offering amniocentesis to the at-risk younger population to detect an additional 20% of Down syndrome pregnancies.

The mental anguish and apprehension that a woman encounters when she is told she is at risk of having a baby with Down syndrome on the basis of a low level of maternal serum α-fetoprotein have been addressed in the literature.[3] The knowledge of this risk plus the thought of having to undergo an invasive procedure (amniocentesis) have been shown to create far more anxiety in the younger woman with a low level of maternal serum α-fetoprotein than in a woman age 35 years and older.[5] Although the anxiety of patients before counseling or prenatal diagnostic testing has been quantified by Evans et al.,[5] the effect of counseling for either alleviation or exacerbation of anxiety has not been previously tested.

Methods

The State Trait Anxiety Inventory designed by Spielberger and colleagues[6] provides a means to measure transitory anxiety levels (i.e., anxiety levels that fluctuate because of external circumstances). The scores obtained on the state anxiety inventory can range from 20 to 80. The greater the level of patient anxiety the higher the score. A slight variation in score indicates large differences in the level of anxiety. The manual that accompanies the test and serves as a guide to score and interpret the state anxiety inventory gives a few examples of anxiety levels. The mean anxiety state of the average medical patient is 42 and the average patient with acute anxiety reaction is 48.

6/1/25238

Private obstetricians or obstetric clinics referred patients to Albany Medical Center after one or sometimes two test results showed low levels of maternal serum α-fetoprotein. Each patient first met with the genetic counselor. After counseling an ultrasonographic evaluation was performed to confirm gestational age, with the option of an amniocentesis if indicated and desired by the patient.

Between Jan. 1 and Oct. 31, 1988, all patients (couples) who were referred for genetic counseling with regard to low levels of maternal serum α-fetoprotein were asked to participate in this study. Two eligible patients refused. Fifty-two patients agreed to take the state anxiety inventory before and after the counseling session. Each patient (couple) met with the counselor for approximately 45 minutes. This time was spent reviewing pertinent information concerning pregnancy and family histories, imparting risk data, and addressing patient questions and concerns. The counselor explained that a low level of maternal serum α-fetoprotein provides an adjustment of a woman's age-related risk of Down syndrome. Patients were also counseled with regard to the impact of gestational age on evaluation of maternal serum α-fetoprotein. Ultrasonographic and amniocentesis procedures were reviewed including the 1 in 250 miscarriage risk associated with amniocentesis.

Our control group consisted of 25 women from the same private obstetric practices as our study group. These women had normal maternal serum α-fetoprotein screening results and were currently being followed up by their obstetricians as low-risk patients. These women were all younger than 35 years of age and from similar socioeconomic, geographic, and educational backgrounds as the women in our study group. Each control patient agreed to participate and complete the state anxiety inventory.

The data were statistically analyzed with the Student *t* test and Mann-Whitney U test.

Results

Our results are summarized in Table I. In our study group, the mean anxiety score when study participants were first seen for counseling was 52. After counseling the mean score dropped to 47 ($p < 0.05$). It is interesting to note that the women initially had much higher anxiety scores than those of their partners (56.5 vs 44.5) and that the women seemed to benefit more from counseling than did the men as evidenced by a greater drop in the anxiety level of the women after counseling (7.0 vs 1.5). The women, when analyzed separately, had a very significant change in anxiety level ($p < 0.01$). However, the men did not experience a significant decrease in anxiety level.

Fig. 1 illustrates the mean anxiety level in the control group versus that in the precounseling and postcounseling groups. The mean anxiety level in our control group was significantly lower than the mean anxiety level in either the precounseling or postcounseling group with low maternal serum α-fetoprotein screening results. It was evident that in general there is elevated anxiety reaction for the patient informed of her increased risk of having a baby with Down syndrome. The control versus precounseling anxiety level is 36 vs 52 ($p < 0.05$). Although the increased anxiety level may persist at least until a definite chromosomal diagnosis by amniocentesis, this initial anxiety can be reduced through comprehensive genetic counseling.

Table I. Summary of results

	Mean anxiety levels			
	Precounseling	*Postcounseling*	*Change*	*p Value*
Participants	52	47	−5	<0.05
Women alone	56.5	49.5	−7	<0.01
Men alone	44.5	43.5	−1.5	>0.05*

*Not significant.

Comment

The maternal serum α-fetoprotein screening test can be a source of patient concern and apprehension. A screening test, independent of maternal age, that would help to identify a subset of pregnancies at risk of an aneuploidy would be of enormous value. The maternal serum α-fetoprotein screening test is not ideal for pregnancies already at risk of an autosomal trisomy.[2] At the maternal serum α-fetoprotein level commonly used for identification of the pregnancies at risk (i.e., calculated risk at 1:270, which correlates with the risk at age 35 years) the sensitivity is approximately 30%. The specificity is also less than ideal. Low levels of maternal serum α-fetoprotein are frequently a result of many factors independent of fetal aneuploidy (incorrect dates, fetal death, choriocarcinoma, elevated maternal weight).

A source of referral for information and guidance should be available to the patient once a low maternal serum α-fetoprotein result is reported. With the use of the state anxiety inventory, we quantified the level of anxiety a low maternal serum α-fetoprotein test result may induce in a patient and the effect that comprehensive genetic counseling can have on this level of anxiety. Counseling reduced the anxiety of these patients. These results contrast with previously published data by Burton[7] in which she investigated anxiety produced by elevated levels of maternal serum α-fetoprotein. She concluded that heightened anxiety was not alleviated by counseling before definitive testing.

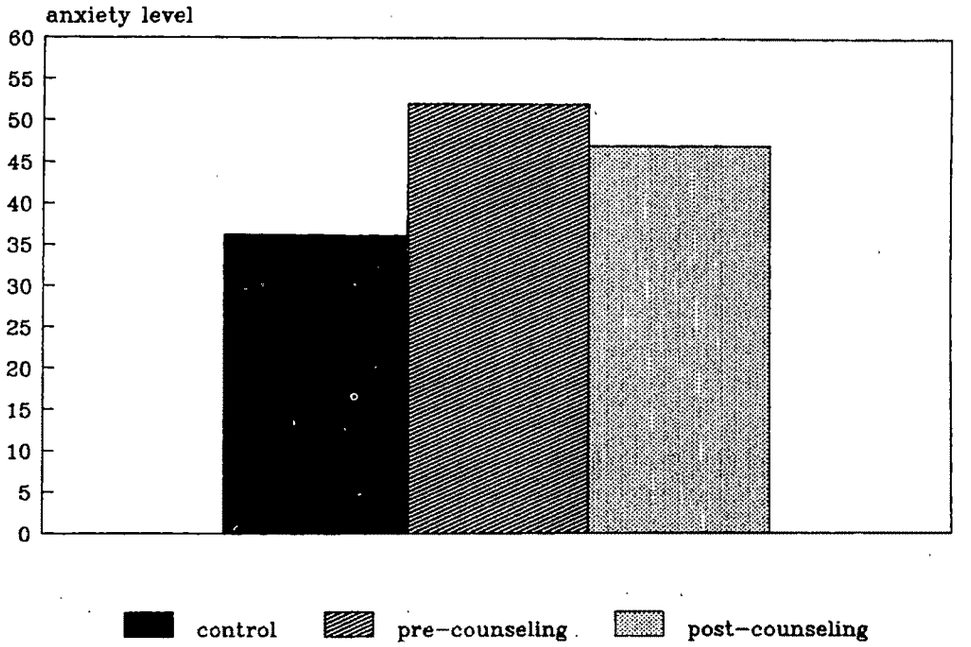

Fig. 1. Mean anxiety.

Although our patients' anxieties were not lowered to levels equivalent to the control group, counseling did significantly reduce their anxiety level. The State Trait Anxiety Inventory was used by both Burton's study and our study. The patients and their partners in our study had an average precounseling anxiety level of 52. In the study by Burton the average anxiety level was approximately 47 and did not change after counseling. In our study, the average anxiety level after counseling dropped to 47. It is possible that our finding of a significant decrease in anxiety level after counseling is attributable to the higher baseline anxiety rate noted in our patients. This higher anxiety level may reflect the patients' perception of the seriousness of the fetal abnormality for which their pregnancy is at increased risk. No data are available to compare perceived risks of neural tube defects with fetal aneuploidy.

In those cases in which amniocentesis reveals a trisomic fetus, it may be said that the cost of the many false-positives was justified. For those pregnancies that are identified, the parents have various options including termination of the pregnancy, exploration of medical and surgical management decisions before delivery, arrangement of an adequate support systems, or just time to cope with the unfulfilled expectation of having a healthy baby. For now, maternal serum α-fetoprotein as a screen for Down syndrome and other trisomies continues to be a controversial issue.

A lower false-positive rate would greatly increase the utility of the screening test and reduce the number of unnecessarily anxious patients. Tests that look at other risk parameters may be integrated into screening programs to improve the sensitivity and specificity of the aneuploidy risk.

Successful antepartum treatment of listeriosis

Charles Kalstone, MD
Miami, Florida

A pregnant patient had a flulike illness at 27 weeks. *Listeria monocytogenes* infection was diagnosed by blood cultures. Electronic monitoring suggested the fetus was stressed. Use of tocolytics inhibited uterine contractions while the mother was treated with intravenous ampicillin. Four days later when labor began because of chorioamnionitis, the infant was delivered in good condition. (AM J OBSTET GYNECOL 1991;164:57-8.)

Key words: *Listeria monocytogenes,* blood cultures, sporadic or epidemic

A case of maternal and fetal *Listeria monocytogenes* infection is reported in which antepartum recognition, uterine tocolysis, antibiotic therapy, and preterm delivery led to a successful outcome.

Case report

A 26-year-old primigravid woman had a normal antepartum course until 27 weeks' gestation when a flulike illness developed with fever, backache, and myalgias. Results of routine urinalysis were normal. After 1 week a blood-tinged, nonpurulent vaginal discharge developed. The membranes were intact, and ultrasonographic examination showed a normal 28-week fetus and placenta. The cervix was not dilated or effaced. The patient was not aware of uterine contractions but external monitoring demonstrated them.

The patient was admitted to the labor room. Except for a temperature of 100.5° F, the physical examination was normal. There were no localizing signs; white blood count was 10,300/mm³ with a normal differential, and hemoglobin was 9.7 gm. Two blood cultures were drawn and vaginal and cervical cultures were taken.

The fetus was active and external monitoring showed a normal fetal heart rate with a reactive pattern. Uterine contractions were mild and occurred every few minutes; administration of two subcutaneous doses of terbutaline, 0.25 mg, 20 minutes apart, stopped them. The cervix remained long and closed. Terbutaline injections were continued every few hours; after 12 hours the drug was given orally at a dosage of 5 mg every 4 hours.

The patient's fever continued and reached 102° F. The bloody vaginal secretions also continued. Two days later the mother reported a lack of fetal movement. External fetal monitoring showed a nonreactive pattern that continued for 12 hours; there were two uterine contractions, each associated with a late deceleration.

Vaginal and cervical cultures were negative but both blood cultures taken on admission were growing *L. monocytogenes.* An infectious disease consultant suggested the use of intravenous ampicillin, which was administered at a dosage of 3 gm every 4 hours. Oral terbutaline was continued, and within 24 hours fetal activity returned to normal.

The maternal fever, flulike symptoms, and bloody discharge from the uterus continued. Three days later labor began and there was active bleeding. The cervix was undilated but effaced. The presentation was vertex. External fetal monitoring demonstrated a reactive fetal heart pattern with no late decelerations despite uterine contractions every 3 minutes. Because the mother was still ill, no further tocolysis was indicated. It was deemed best to deliver the infant promptly, while it had recovered from the intrauterine stress.

A low vertical cesarean section was performed with the mother under epidural anesthesia. The placenta was necrotic; microscopically it contained microabscesses, villositis, acute chorioamnionitis, and umbilical angiitis. Culture of the membranes revealed light growth of *L. monocytogenes.*

The infant, a 1100 gm male, had Apgar scores of 6 at 1 minute and 8 at 5 minutes. He was intubated in the delivery room, transferred to the neonatal intensive care unit, and received mechanical ventilation and oxygen for moderate respiratory distress syndrome. His white blood cell count was 32,000/mm³ with 45 bands, consistent with intrauterine infection. He was treated with ampicillin and gentamicin. On day 3 his white blood cell count was 70,000/mm³ with 30% monocytes. Cultures of his blood, gastric and tracheal aspirates, and spinal fluid were negative. When he was extubated on day 6, he became acutely hypoxic as a result of a pulmonary hemorrhage. He was immediately reintubated and there was no further pulmonary bleeding. Ultrasonography showed no intracranial hemorrhage. Five days later he was reextubated and did well. Intravenous ampicillin was given for 14 days. He was discharged in excellent condition on day 50, weighing 1940 gm.

The mother's illness resolved with delivery. She was discharged in 1 week and was treated with intravenous ampicillin for an additional 2 weeks.

Comment

Listeria infections occur primarily in pregnant women, newborns, elderly, and immunocompromised persons. A flulike illness that persists in a pregnant patient, especially in the third trimester, can be caused by *L. monocytogenes* infection. Cervical and vaginal cultures often show no growth of this organism. For this reason, blood cultures are the best means to establish the diagnosis. The infection is bloodborne and spreads to the fetoplacental unit.

Untreated listeriosis has a high perinatal morbidity and mortality. Prompt maternal antibiotic therapy can save the fetus in utero. Intravenous ampicillin is the treatment of choice; it achieves desirable drug levels in the fetus. In penicillin-allergic patients, use of sulfamethoxazole and trimethoprim has been successful.

Cases of listeriosis are sporadic or epidemic. When sporadic, the source is usually not determined. Our patient ate imported Gouda cheese around the time that she became ill but none was left to test for listeria infection. There have been reports of epidemic outbreaks of listeriosis acquired from eating cheese made from unpasteurized milk.[1] Pregnant patients should be warned not to eat cheese made from unpasteurized milk. Improper curing, another alternative in cheesemaking, may not kill the listeria organism.

Others have reported successful antibiotic treatment of maternal listeria septicemia in the second trimester with resultant delivery of a normal infant at term.[2] The unique aspects of this case report are that tocolytics were used to inhibit preterm uterine contractions while maternal antibiotic therapy reversed the fetal stress demonstrated by external fetal heart monitoring. However, administration of antibiotics did not cure the mother. Fever persisted, as did bloody discharge from the uterus, an important sign that is probably caused by placental necrosis from intrauterine infection. This can cause labor by release of prostaglandins from the decidua and membranes.

In cases like this one, when it may not be possible to continue to inhibit preterm labor by tocolytics, initiating maternal antibiotic therapy may control fetal infection until the infant is born. Antibiotic therapy then can be continued in the neonate. Although uncommon, listeriosis is a preventable cause of perinatal mortality.

I thank William J. Ledger, MD, professor and chairman, Department of Obstetrics and Gynecology, Cornell Medical Center, New York, for his assistance.

Anemia and spontaneous preterm birth

Mark A. Klebanoff, MD, MPH,[a] Patricia H. Shiono, PhD,[a, b] Joseph V. Selby, MD, MPH,[c] Alan I. Trachtenberg, MD, MPH,[d] and Barry I. Graubard, MA[e]

Bethesda, Maryland, and Oakland, California

The association between anemia during pregnancy and spontaneous preterm birth was studied with a two-stage case-control design in a large, multiethnic cohort. Results of all hematologic measurements were abstracted from the prenatal and delivery records of 1706 of the 26,901 women in the cohort. Among women delivered of infants at term, mean hematocrit value was low during the early phase of the second trimester, stable until near term, then reached a maximum at 40 weeks' gestation. The mean hematocrit value of black women was consistently lower than that of Asian, Mexican, and white women. Anemia (hematocrit value less than the tenth percentile for ethnic group and duration of pregnancy) at any time during the second trimester was positively associated with subsequent spontaneous preterm birth (odds ratio, 1.9; 95% confidence interval, 1.3 to 2.8). Compared with white women, the odds ratios for preterm birth were 2.0 (95% confidence interval, 1.6 to 2.4) for black, 1.2 (95% confidence interval, 0.9 to 1.6) for Asian, and 1.2 (95% confidence interval, 1.0 to 1.5) for Mexican women. Adjustment for second-trimester anemia had minimal influence on the odds ratios. We conclude that anemia during the second trimester was associated with preterm birth. However, it does not account for the large ethnic differences in preterm birth. (AM J OBSTET GYNECOL 1991;164:59-63.)

Key words: Anemia, hematocrit, pregnancy, premature labor

Anemia, as measured at the time of delivery, has been associated with spontaneous preterm birth.[1, 2] The study reported that a hematocrit value of 34 or less was strongly associated with preterm birth and that there was a dose-response relationship between hematocrit value and preterm birth. Anemia was found to account for 60% of the observed differences between black and white women in the occurrence of spontaneous preterm birth.[1] These findings were later questioned in a subsequent study[3] that showed that because the hematocrit value rises during the third trimester of a normal pregnancy, comparison of delivery hematocrit values in women giving birth to term and preterm infants produces a spurious association between anemia and preterm birth. The purpose of the present study is to explore further the association between hematocrit measured at various gestational ages before delivery and duration of pregnancy. To accomplish this, a case-control study[4, 5] was carried out within a large, multiethnic pregnancy cohort.

Methods

The data for this study are from the northern California Kaiser Permanente Birth Defects Study. Detailed methods of this prospective cohort study are published elsewhere.[6] Women who registered for prenatal care at the 13 facilities that served northern California during 1974 to 1977 completed a self-administered questionnaire in English or Spanish that obtained information on a variety of demographic, reproductive, and behavioral variables. Gestational age was determined on the basis of the menstrual history and physical examination at the first prenatal visit. Preterm delivery was defined as a live birth of 24 to 36 completed weeks' gestation. There were 36,504 women initially recruited; exclusion of women found not to be pregnant, women who had induced abortions, women who wanted the infant to be adopted, women not delivered of infants at a Kaiser hospital, and women lost to follow-up resulted in outcome data for 34,660 babies. Women delivered of a live-born singleton infant of at least 24 weeks' gestation and 500 gm were included in these analyses (n = 31,682). Repeat study pregnancies by the same women were excluded (n = 1086), as were women who started prenatal care after 24 weeks' gestation (n = 2266) and women of unknown race (n = 1429). The final sampling frame contained 26,901 women.

In the original study, data on hematocrit values and whether delivery was induced were not collected. So

*Values were used to adjust the odds ratios for ethnicity and preterm birth and the adjustments to their variances.

†Derived by multiplying the quotient of the number of women with known spontaneous preterm labor with one or more hematocrit values (a), divided by the sum of the number of women with known spontaneous preterm labor with one or more hematocrit values (a) and the number of women with known induction or no labor (b), times the number of women in the full cohort (c): $[a/(a + b)] \times c$.

that these data could be gathered by review of the records of a manageable number of preterm and term pregnancies, a two-stage case-control design was used.[4, 5] All preterm infants born to Asian (n = 152), black (n = 306), and Mexican (n = 243) women were selected, as was a simple random sample of 401 of the 1194 preterm infants born to white women. Within each ethnic group, one control woman delivered of an infant after 36 weeks' gestation was selected at random for each case. Hematocrit data were abstracted from both the inpatient and outpatient records; data on induction of labor were abstracted from the inpatient records.

Of the 2204 women in the sample, charts for 334 were not available, primarily because of off-site storage and personnel shortages at certain facilities. Therefore women with missing charts are unlikely to differ from the remainder of the sample. Inasmuch as spontaneous preterm birth was the outcome of interest, preterm infants born after induced labor or cesarean section in the absence of labor were excluded (n = 164), which reduced the number of records to 1706. The final sample analyzed consisted of women who had spontaneous preterm labor and one or more hematocrit values (n = 94, Asian; 198, black; 159, Mexican; 274, white), or term delivery and one or more hematocrit values (n = 140, Asian; 279, black; 200, Mexican; 362, white). Details of the sampling procedure are shown in Table I.

All measures of hematocrit or hemoglobin and the date they were obtained were abstracted from the records. Data on the source of blood (venous or finger stick), the method used to calculate hematocrit (centrifuged or Coulter counter) and the cause of anemia (iron deficiency or other) were not obtained. The gestational age at each measurement was determined by subtracting the date of the last menstrual period or physician's estimate of the last menstrual period from the date the blood was obtained. On average, each woman had 2.6 measures of hematologic status; 12% had one measure, 31% had two, 36% had three, 17% had four, and 4% had five or more. In those instances in which only a hemoglobin value was available, it was converted to an equivalent hematocrit value by multiplying by three.

Our definition of anemia varied slightly depending on the specific analysis. When the relationship between anemia and subsequent preterm birth was studied, ethnic group-specific definitions of anemia were used to separate the effect of anemia from that of ethnicity. Thus for each ethnic group anemia was defined as a hematocrit value of less than the tenth percentile for women of that ethnic group during each 2-week interval of gestational age on the basis of the measurements of pregnancies that ultimately ended at term. The distribution of hematocrit values was similar for all nonblack women; therefore these groups were combined. The distribution of hematocrit values among black women was shifted toward lower values. Dependent on the specific interval, the tenth percentile of hematocrit was 31 to 33 for nonblack and 29 to 31 for black women.

When the role of anemia in explaining the ethnic differences in preterm birth was studied, anemia was defined as the tenth percentile for all term infants in the sample, weighted for the unequal sampling probabilities of each ethnic group. If different tenth percentiles were used for each ethnic group, the prevalence of anemia would not differ between ethnic groups and adjustment for anemia could not effect the relationship between ethnicity and preterm birth.

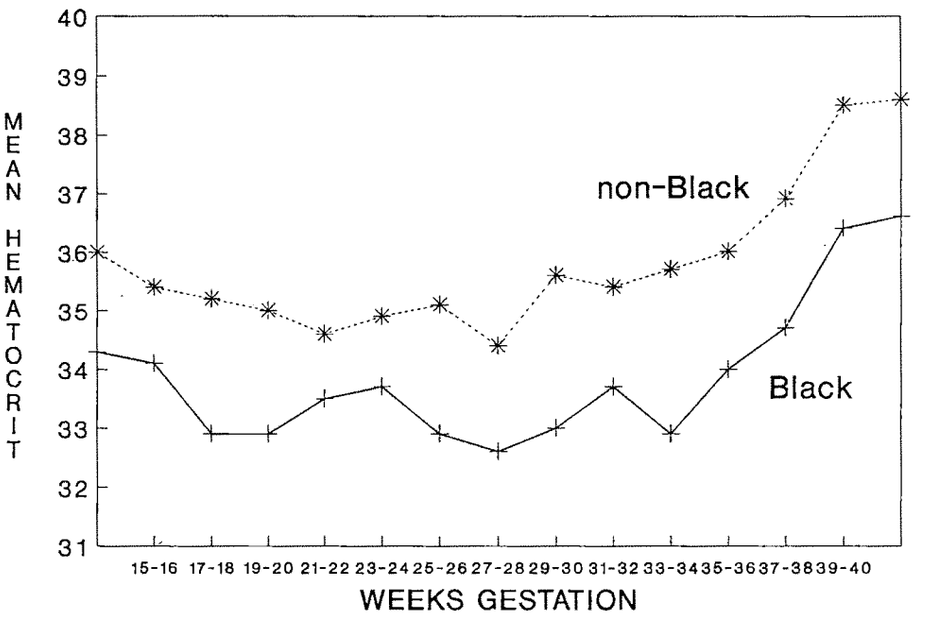

Fig. 1. Mean hematocrit value at each 2-week interval of gestation among pregnancies delivered at term.

Statistical methods. As described, all Asian, black, and Mexican preterm infants were studied, as were approximately one third of the white preterm infants. Term infants were selected as controls from each ethnic group according to the number of preterm cases from that group. Because the sampling probabilities were known and differed by outcome and ethnic group, odds ratios for ethnicity could be calculated by adjusting for the different sampling fractions according to the method described by Cain and Breslow.[5] This method adjusts both the odds ratios and the SEs derived from logistic regression for unequal sampling probabilities.

To compare our results with those previously described,[3] the change in hematocrit value during a normal pregnancy that resulted in a term infant was evaluated. The mean hematocrit value at each 2-week interval during the second and third trimesters for women delivered of infants of >36 weeks' gestational age was studied. Next, we evaluated the association between anemia as determined at each 2-week interval of gestational age and subsequent preterm birth. In addition, the occurrence of preterm birth was compared between women who were anemic at any time during the second trimester and women who had hematocrits measured during the second trimester and were not anemic. This analysis was done for all women and separately for women in each ethnic group. Finally, we evaluated the role of anemia in explaining the ethnic differences in preterm birth. The odds ratios were calculated for preterm birth to Asian, black, and Mexican women compared with white women. The contribution of differing rates of anemia to the ethnic differences in preterm birth was assessed by comparison of the odds ratios before and after adjustment for the presence of anemia at any time during the second trimester. Logistic regression was used for these analyses.

Results

The mean hematocrit value at each 2-week interval of gestation during the second and third trimesters is presented in Fig. 1 for black and nonblack women delivered of infants at term. Hematocrit values appeared to fall during the early second trimester, reach a nadir at approximately 26 to 28 weeks' gestation, begin to increase again at 31 to 33 weeks, then increase sharply at term, reaching a maximum at 40 weeks' gestation. Throughout the second and third trimesters, hematocrit values were approximately 2% lower among black than among nonblack women.

Because hematocrit values varied widely by gestational age, the relationship between preterm delivery and anemia was evaluated at 2-week intervals of gestational age (Table II). Odds ratios for preterm birth and anemia were adjusted for ethnicity, age, education, marital status, smoking, and gestational age at first prenatal visit. The odds ratios for anemia during the period from 13 to 26 weeks' gestation were >1.0, indicating an increased risk of preterm delivery among anemic women. However, anemia after 26 weeks' gestation generally had an inverse relationship with preterm birth. Having been anemic at any time during the second trimester (weeks 13 to 26) was positively asso-

†$p < 0.05$.

ciated with preterm birth [odds ratio, 1.9; 95% confidence interval (CI) 1.2 to 3.0]. The odds ratios by ethnic group were 2.6 (95% CI, 0.7 to 9.6) for Asian women, 1.8 (95% CI, 0.9 to 3.6) for black women, 2.0 (95% CI, 0.8 to 4.7) for Mexican women, and 1.8 (95% CI, 1.0 to 3.5) for white women. Anemia at any time during the third trimester was not analyzed because women delivered of infants at term had more opportunity than did women delivered of infants before term to have anemia diagnosed. This does not apply to the biweekly analyses in Table II because only women who were still pregnant during that interval could have their hematocrit measured.

The role of anemia in the explanation of the ethnic differences in preterm birth is shown in Table III. The unadjusted odds ratios for preterm delivery among Asian, black, and Mexican women, compared with white women were 1.2, 2.0, and 1.2, respectively. Despite the association between second-trimester anemia and preterm birth, adjustment for the presence of anemia at any time during the second trimester had little effect on the ethnic differences in preterm delivery. Anemia after 26 weeks' gestation was negatively associated with preterm birth; therefore it could not possibly account for the observed ethnic differences.

Comment

We found that in pregnancies carried to term, the mean hematocrit value rises dramatically after 37 weeks' gestation. This is in agreement with earlier reports,[3] and with the standards developed by the Centers for Disease Control for hematocrit values during pregnancy.[7] Because the same group of women contributed data over most of pregnancy, our study has advantages over purely cross-sectional data in which entirely different women may have had blood drawn during each interval. However, our data are not fully longitudinal; every woman did not have an hematocrit drawn during every interval. To the extent that women who had blood drawn during any given interval differed from those who did not, our results will be in error. Our results agree closely with established standards,[7] and are consistent with the observation that plasma volume is relatively constant after 34 weeks' gestation but red cell mass increases linearly throughout pregnancy.[8] This suggests that the lack of regular measurements taken longitudinally on each woman was unlikely to influence the results.

Our results confirm those of Klebanoff et al.,[3] who found that when measured prospectively, third-trimester anemia was not a risk factor for preterm birth. Our results contradict those of Lieberman et al.,[1] who found a very strong dose-response relationship between preterm birth and third-trimester anemia (hematocrit value ≤34) and that anemia accounted for much of the difference in preterm delivery rates between black and white women. Lieberman et al.[1] defined anemia with hematocrit values obtained at delivery. Our data suggest that the use of delivery hematocrit values is inappropriate because hematocrit rises sharply at term. Use of delivery hematocrit values will therefore produce a spurious relationship between anemia and preterm birth.

We found a moderate relationship between anemia during the second trimester and preterm birth. Anemia during the third trimester tended to be negatively associated with preterm birth. In addition, we found that statistical adjustment for the presence of anemia did not affect the ethnic differences in preterm delivery previously reported in this cohort.[9] The association between second-trimester anemia and preterm delivery is not inconsistent with previous findings on this subject because prior work did not evaluate anemia during the second trimester.[3]

Why should second-trimester anemia be associated with preterm delivery when anemia later in pregnancy is not? There is no clear answer. This association has not been reported previously, and it may be an artifact of multiple comparisons. The relationship was consistent within ethnicity, making simple chance less likely. It is possible that a small group of high-risk, severely anemic women had hematocrits measured on multiple occasions. This detection bias would tend to overstate the relationship between preterm birth and anemia. We found that women who had one hematocrit measured during the second trimester were no more likely to be delivered of preterm infants than were women who had none. However, women who had two or more hematocrit measurements during the second trimester were at elevated risk of preterm delivery. In an attempt to reduce detection bias, we analyzed mean and first hematocrit values during the second trimester. The results were unchanged when anemia was defined with the use of the mean of all hematocrit values obtained during the second trimester and with the first hemat-

ocrit value obtained during the second trimester. Nevertheless, the association between anemia during the second trimester preterm birth should be considered tentative and needs to be confirmed in other populations.

A precise definition of anemia during pregnancy is confounded by various factors such as altitude, ethnicity, use of iron supplements, and changes in plasma volume during pregnancy. Definitions of anemia have ranged from hematocrit values of ≤34,[1] to a hemoglobin of <10 gm per deciliter[10] (corresponding to hematocrit value of 30), to the Centers for Disease Control's month-specific standards.[7] Use of either of the two fixed values (≤34 or <30) produced similar results in our data. Because there is no standard definition of anemia for 2-week intervals during pregnancy, we chose to use the internal standard of the tenth percentile at each 2-week interval, as determined among pregnancies that ultimately resulted in births at term. When evaluating the role of anemia, separate standards were used for black and nonblack women to eliminate ethnicity as a confounder. When evaluating the role of ethnicity in preterm birth, a single standard for anemia was used so as not to overadjust for ethnicity.

Rapid changes in red cell mass and plasma volume during pregnancy make interpretation of isolated hematocrit values difficult. Low hematocrit levels may result from inadequate red cell mass or a large expansion of plasma volume. Inadequate expansion of plasma volume, which would result in high hematocrit values, has been associated with an increased risk of a variety of pregnancy complications.[11, 12] Women with normal red blood cell mass and a large expansion of plasma volume would probably be at low risk of adverse outcome despite an apparent anemia. Therefore further studies with clinical determinations of hematocrit value are unlikely to resolve this issue. Anemia in pregnancy should be defined as a function of red cell mass and plasma volume, neither of which are measured in clinical settings. In addition, measured hematocrit is a result of the interaction of physiologic, nutritional, and other life style factors. Despite any observed associations, low hematocrit values may merely be a marker for social and environmental deprivation, rather than being a cause of preterm birth. Therefore treatment of anemia alone might not affect the occurrence of spontaneous preterm birth.

In conclusion, anemia during the second trimester was found to be positively associated with spontaneous preterm birth; anemia later in pregnancy tended to be negatively associated with preterm birth. Second-trimester anemia did not contribute to the observed ethnic differences in the occurrence of preterm birth. Future studies of anemia during pregnancy should supplement routine clinical data with detailed measures of red cell mass and plasma volume. These additional measurements may clarify the role of anemia in the pathogenesis of preterm birth as well as explain the observed ethnic differences in hematocrit values.

We thank Dr. Sholom Wacholder of the National Cancer Institute for his assistance with the sampling method and Ms. Marilyn Goldhaber for her assistance in the development of this project.

Fetal urine output does not influence residual amniotic fluid volume after premature rupture of membranes

William J. Watson, MD, Vern L. Katz, MD, and John W. Seeds, MD
Chapel Hill, North Carolina

Fetal urine production in 12 women with premature rupture of membranes did not differ from that of a control group, and there was no correlation between fetal urine output and residual amniotic fluid volume. Residual amniotic fluid volume after premature rupture of membranes does not appear to depend on or alter fetal renal function. (AM J OBSTET GYNECOL 1991;164:64-5.)

Key words: Premature rupture of membranes, amniotic fluid, fetal urination

Pregnancies complicated by preterm premature rupture of membranes are at increased risk for adverse outcome if the residual amniotic fluid volume is low. Urine production may also depend on fetal oral intake, which may be reduced with low amniotic fluid volumes. We hypothesized that residual amniotic fluid volume in pregnancies complicated by premature rupture of membranes may be related to fetal urine production.

Methods

This study was approved by the institutional committee on research of human subjects. Fetal urine output was estimated ultrasonographically by the method of Campbell et al.[1] in 12 gravid women with premature rupture of membranes at 26 to 34 weeks' gestation and compared with similar estimates in a control group of 12 women with uncomplicated pregnancies of similar gestational ages and with intact membranes. The bladder was measured in three dimensions, and the product of these measurements was multiplied by $\pi/6$. The fetal bladder was observed with ultrasonography over a period of 30 to 60 minutes for each determination. The values for two determinations were averaged in determining urine output. In the study group the estimations were made an average of 3.4 ± 1.7 days (range 0.5 to 7 days) after hospitalization for ruptured membranes, while patients were in the hospital at bed rest. The control group consisted of low-risk pregnant patients, matched for gestational age, with singleton gestations and no medical complications, who were recruited from our obstetric practice. In the women with intact membranes estimations were made after rest for at least 30 minutes. No patients in the study were taking medications, other than prenatal vitamins and iron.

Statistical analysis between groups was done with Student's t test for variables with equal but unknown variances or by use of the method of least squares for simple linear regression, where appropriate.

Table I. Ultrasonographically determined fetal urine output

	Ruptured membranes	*Intact membranes*
Estimated weight (gm)	1616	1679
Urine output (ml/kg/hr, mean ± SEM)	11.5 ± 5.3	10.8 ± 4.3*

*$t = -0.36$; $p > 0.50$.

Results

Fetal urine output in the women with ruptured membranes (11.5 ± 5.3 ml/kg/hr) was not significantly different from the mean fetal urine output in the control group (10.8 ± 4.3 ml/kg/hr, Table I). Furthermore, there was no significant correlation between amniotic fluid index and fetal urine output ($r = -0.22$, $p = 0.49$). A power analysis showed that the sample size was sufficient to detect a 50% reduction in fetal urine output in the premature rupture of membranes group with a type II error of <20%.

Comment

The prognosis for the fetus in pregnancies complicated by preterm premature rupture of membranes may be related to residual amniotic fluid volume. Factors that influence residual amniotic fluid volume after rupture of membranes are poorly understood. Fetuses in pregnancies complicated by premature rupture of

membranes may have an increased risk of intrauterine growth retardation. Wladimiroff and Campbell[2] studied urine production in fetuses with intrauterine growth retardation and found that urine output was much lower than that expected for a normally grown fetus in three of 12 determinations.

In this study fetal urine output in pregnancies complicated by premature rupture of membranes was not reduced and did not vary as a function of residual amniotic fluid volume. Fetal urine production was unchanged even in the presence of severe oligohydramnios. We conclude that residual amniotic fluid volume after premature rupture of membranes does not depend on, or alter, fetal renal function. Residual amniotic fluid volume may depend on mechanical factors, such as maternal position, the site of leakage, and the size of the defect in the fetal membranes.

The diagnosis of ovarian cancer by pathologists: How often do diagnoses by contributing pathologists agree with a panel of gynecologic pathologists?

Carl W. Tyler, Jr., MD,[a] Nancy C. Lee, MD,[b] Stanley J. Robboy, MD,[c] Robert J. Kurman, MD,[d] Allen L. Paris, MD,[e, f] Phyllis A. Wingo, MS,[b] and G. David Williamson, PhD[g]

Atlanta, Georgia, Newark, New Jersey, Baltimore, Maryland, and West Plains, Missouri

The Cancer and Steroid Hormone Study, a multicenter, population-based, case-control study of ovarian, breast, and endometrial cancer in women 20 to 54 years of age, permitted the diagnoses of contributing pathologists to be compared with those of a panel of three gynecologic pathologists. A diagnosis of ovarian cancer was made by contributing pathologists on 477 subjects. Agreement between the two groups of pathologists was 97% for primary epithelial ovarian cancer and 89% for primary nonepithelial ovarian malignancies. Agreement on diagnosis of major cellular subtypes of ovarian malignancy ranged between 73% for endometrioid cancer and 100% for clear cell carcinomas. We conclude that the diagnosis of pathologic features of primary ovarian cancer is highly predictable. Nonetheless, diagnosis by histologic type varies sufficiently that a review process should be considered for clinical or investigative decisions involving specific histologic diagnoses of ovarian cancer. (Am J Obstet Gynecol 1991;164: 65-70.)

Ovarian cancer is a significant cause of death for women in the United States. In 1989 an estimated 20,000 American women were newly diagnosed as having ovarian cancer, and 12,000 died from this malignancy.[1] The diagnosis of ovarian cancer by pathologists not only guides patient treatment but also provides the basis for evaluation of different approaches to treatment in multicenter clinical trials and in epidemiologic studies of risk factors. As an illustration, if a cancer that metastasized to the ovary were not diagnosed correctly on a pathology report, the patient might be treated as if the tumor were primary in the ovary when another site was the one of origin; this might lead to inappro-

priate therapy. If this occurred often enough, studies that evaluate surgical or chemotherapeutic approaches to primary ovarian cancer would incorrectly include tumors from other organs. This problem would also extend to epidemiologic investigations of the causes of ovarian cancer.

In the period 1980 to 1982 the Centers for Disease Control, with support from the National Institute of Child Health and Human Development and from the National Cancer Institute, conducted the Cancer and Steroid Hormone Study, a multicenter, population-based case-control study of ovarian, breast, and endometrial cancer in women 20 to 54 years of age.[2, 3] The study provided the opportunity to compare the diagnoses of ovarian malignancies made by contributing pathologists with those of a panel of three gynecologic pathologists. In this article we describe a measure used to make quantitative comparisons of the diagnoses, give a brief review of the methods used in the Cancer and Steroid Hormone Study, and report our findings.

Background

The accuracy of diagnostic tests, as exemplified by surgical pathology reports, has always been important. Even though we have always known that no diagnostic test is perfect, most of us assume that if an accurate diagnostic test for a particular condition does exist, it must be one reported by a skilled pathologist. Nonetheless, scientific articles have documented discrepancies among pathologists in the diagnosis of ovarian cancer.[4-7]

Investigators now quantify these discrepancies. In this report we will focus on the predictive value positive[8] as the measure for evaluation of diagnoses of histopathologic features of ovarian cancer. The predictive value positive is a measure of the probability that disease exists, given that the report of a diagnostic test is positive. It can be calculated with a numerator of patients known by a widely accepted, highly accurate standard to have ovarian cancer, who also have a histopathology report positive for ovarian cancer. The denominator is all the histopathology reports of ovarian cancer, regardless of whether all the patients included have disease. (Other measures of the characteristics of diagnostic tests include sensitivity, specificity, and predictive value negative. They are not included here because they require information about negative test reports and the absence of disease not reflected in the data we analyzed.)

In analyzing the predictive value positive of reports for a disease, the reports of interest (in this case, those of ovarian cancer) need to be compared with an acceptable standard. In this analysis we compared the reports of ovarian cancer made by all pathologists in the geographic area of each of the Surveillance, Epidemiology, and End Results (SEER) centers who contribute their reports (designated as contributing pathologists hereafter) with the consensus diagnosis of the panel of pathologists. In calculating the predictive value positive, the reports of the contributing pathologists serve as the denominator. Those confirmed by the panel are the numerator. Therefore, if 50 cases were reported to be ovarian cancer by SEER centers on the basis of the reports given them by contributing pathologists, but the panel confirmed only 45 of them, then the predictive value positive would be as follows:

$$PVP = 45/50 \times 100 = 90\%$$

Methods

The general methods of the Cancer and Steroid Hormone Study have been described previously.[2, 3] Subjects included in this analysis were enrolled through population-based tumor registries participating in the SEER program of the National Cancer Institute in six areas of the United States in which both interviews and retrieval of histopathology reports could be done (the metropolitan areas of Atlanta, Detroit, San Francisco, and Seattle, and the states of Connecticut and Iowa).

The subjects of this analysis were all women with primary ovarian cancer 20 to 54 years of age who resided in any of the reporting areas and who were first diagnosed as having ovarian cancer in the period Dec. 1, 1980, to Dec. 31, 1982. Of the 816 women who satisfied the case definition for ovarian cancer in the original Cancer and Steroid Hormone Study, 579 (71%) were interviewed. Slide retrieval was attempted only for the interviewed study subjects. Because only the six SEER centers mentioned in this article participated in retrieval of the slides of histologic specimens, the 40 women with ovarian cancer interviewed for the study from the other two centers (those in New Mexico and Utah) were excluded from this analysis. Furthermore, 62 additional subjects could not be included for the following reasons: slides could not be retrieved (18), inadequate specimens (8), possible previous history of ovarian cancer (4), and original diagnosis of the contributing pathologist not available (32). Therefore the subjects in this analysis included 477 women with primary ovarian malignancy as diagnosed by pathologists participating in the aforementioned population-based cancer registries.

All slides of histopathologic specimens were initially read by the contributing pathologists, and the results were then reported to the SEER centers. Because the tumor registries are population-based, the pathologists making these initial readings represent those practicing in the entire community.

Slides that were the basis for the original diagnosis made in the community in which the study subjects

Table I. Histopathologic diagnosis by contributing pathologists compared with those of a panel of gynecologic pathologists, by histologic category of ovarian tumor*

Contributing diagnoses	*Total*	*Benign*	*Panel diagnoses†*		
			Epithelial cancer	*Nonepithelial cancer*	*Metastatic cancer*
Epithelial cancer	432	1	420	2	9
Nonepithelial cancer	45	1	4	40	0
TOTAL	477	2	424	42	9

*A total of 62 subjects are excluded from this table because of the following reasons: 32 diagnoses not available, 18 slides not retrieved, 8 inadequate slides, and 4 subjects with a previous or uncertain history of ovarian cancer.

†Predictive value positive for all ovarian primary cancers [(424 + 42)/477] = 98%; predictive value positive for epithelial ovarian cancer (420/432) = 97%; predictive value positive for nonepithelial ovarian cancer (40/45) = 89%.

lived were then reviewed by a panel of three pathologists expert in the diagnosis of histopathologic features of ovarian cancer (Drs. Robboy, Kurman, and Paris). When required the panel requested additional slides for review. The panel reviewed each histologic specimen independently. If there were differences in the reviews of panel members, individual specimens were reviewed in greater detail with a microscope with eyepieces that permitted the panelists to examine and discuss each specimen simultaneously until consensus was reached. No written record of such differences were kept by the panel because the differences occurred so infrequently.

Each ovarian tumor was categorized by the panel as malignant (primary), malignant (metastatic), or benign. The malignant primary tumors were then classified as epithelial or nonepithelial, and assigned a histologic type including characterization as malignant or low malignant potential (borderline). Tumors of low malignant potential were grouped with malignant tumors when analyzed by histologic type. The classification scheme used was that of the World Health Organization.[9] In analyzing differences, trivial discrepancies in wording, such as papillary serous rather than serous, were not considered different. Further, as many ovarian tumors show blends of features (e.g., serous and endometrioid) the panel attempted not to consider such diagnoses as different from those reported by the contributing pathologists unless the discrepancy was readily apparent. In 79 cases a substantial portion of the tumor warranted a second diagnosis. Both diagnoses were considered in assessing concurrence between contributing and panel pathologists.

Statistical differences between predictive value positives were evaluated with χ^2 tests.[10] These differences were regarded as significant for $p < 0.05$.

Results

Among the women with primary ovarian tumors, approximately one third (35%) were in the age range 20 to 39 years; one third (34%) 40 to 49 years; and one third (32%) 50 to 54 years at the time of diagnosis. (Design of the Cancer and Steroid Hormone Study excluded women older than 54 years.) Almost 90% (88%) were white. Slightly more than four fifths (83%) were high school graduates. Approximately one quarter (26%) were nulliparous. More than 40% were no longer menstruating regularly.

In this investigation, the contributing pathologists diagnosed 477 tumors as primary ovarian cancer, and the panel pathologists agreed with 466 (98%), as shown in Table I. The predictive value positive for epithelial cancers (97%) is significantly greater than that for nonepithelial neoplasms (89%, $p < 0.05$). For cancer of low malignant potential (borderline), the predictive value positive is 93%, whereas that for invasive cancer is 85% ($p < 0.05$, Table II).

Contributing pathologists and the panel of gynecologic pathologists agreed on the histologic type of ovarian cancer less often than they did on the diagnosis of malignancy. In this analysis we considered four specific types of epithelial ovarian cancers. There were too few cases of the other types of epithelial ovarian cancer to be included. Table III shows the panel agreed with the 21 cases originally diagnosed by the contributing pathologists as clear cell carcinoma. The remaining three histologic types—serous, mucinous, and endometrioid—all had predictive value positives significantly lower than that for clear cell cancers ($p < 0.05$), but not different from each other. The two types of nonepithelial cancer—germ cell and sex cord—had predictive values of 92% and 88%, respectively; these values are not significantly different from each other or from the predictive value positives for the serous, mucinous, or endometrioid tumors.

The disagreements between the contributing pathologists and the expert panel focused on three issues. First, of the 11 instances in which the contributing and panel pathologists did not agree on the diagnosis of primary ovarian cancer (Table I), nine were diagnosed as metastatic tumors by the panel. Next, of the 63 cases in which disagreement occurred on the diagnosis of

Table II. Histopathologic diagnoses of ovarian cancers by contributing pathologists compared with those of a panel of gynecologic pathologists, by low malignant potential (borderline) and invasive cancer*

Contributing diagnoses	*Total*	*Predictive value positive (%)*	*Panel diagnoses*	
			Agree	*Do not agree*

Invasive cancer	378	85	321	57

$p < 0.05$.

*Excludes 11 cases judged benign or metastatic and two diagnoses not available.

Table III. Histopathologic diagnoses by contributing pathologists compared with a panel of gynecologic pathologists by histologic type of ovarian cancer*

Contributing diagnoses	*Total*	*Predictive value positive (%)†*	*Panel diagnoses*	
			Agree	*Do not agree*
Serous	256	80	205	51
Mucinous	85	87	74	11
Endometrioid	52	73	38	14
Clear cell	21	100	21	0
Germ cell	24	92	22	2
Sex cord	17	88	15	2
Overall	455	82	375	80

*A small number of other types of epithelial (8) and nonepithelial (3) ovarian cancers are not included in this tabulation. The 11 metastatic and benign tumors shown in Table I are also excluded from this table.

†See text for discussion of the significance of the differences in predictive value positive values.

low malignant potential or borderline (Table II), the panel made a diagnosis of low malignant potential rather than invasive cancer in 57 (90%) and a diagnosis of invasive malignancy in six (10%) instead of low malignant potential. In this group of 63 cases, there was substantial concurrence on cell type. Finally, analysis of histologic type showed that the panel did not agree with the diagnosis of the contributing pathologists in 85 instances. In more than half of these cases (48 or 56%) the disagreement involved the distinction between endometrioid and serous cancer. In 36 instances the diagnosis of contributing pathologists was serous carcinoma, whereas the diagnosis of the panel pathologists was endometrioid cancer; the diagnoses were made in the reverse order for the other 12 instances.

An analysis of interview data showed that differences in diagnoses between the contributing pathologists and the panel of experts were not related to geographic region, age, race, menopausal status, estrogen use, use of oral contraceptives, or history of infertility.

Comment

This analysis highlights three findings. First, a diagnosis of primary ovarian cancer by contributing pathologists agreed with that of the panel in 98% of cases included in the Cancer and Steroid Hormone Study. In fact, of 477 cases reported as ovarian cancer, only two were judged by the panel to be benign; the remaining nine cases were diagnosed by the panel as metastatic (i.e., not primary ovarian cancer). Next, tumors of low malignant potential and invasive cancer were also differentiated with high (93% and 85%, respectively), albeit significantly different, levels of agreement. Of the cases on which there was disagreement, the panel diagnosed 90% (57 of 63) as tumors of low malignant potential rather than invasive cancer. Finally, the panel agreed with the contributing pathologists on 100% of cases reported to be clear cell ovarian carcinoma, but overall agreement on histologic type of tumor (375 of 455, or 82%) did not reach the same level attained in the correct diagnosis of primary ovarian cancer, or in the differentiation of tumors of low malignant potential from invasive cancer.

There are several limitations of this analysis. First, it is based on data from a study that focused on the epidemiologic relationship of cancers of the ovary, breast, and endometrium with administration of steroid hormone to women 20 to 54 years old. Therefore questions concerning ovarian cancer pathologic findings were not of highest priority. If they had been, the study design would almost surely have been different (e.g., it might have included women of all ages). Next, the pathologists on the panel knew the original diagnoses made by the contributing pathologists. We cannot be sure that this introduced bias into our results, but if it did it probably increased the predictive value positive. Fi-

Table IV. Summary of reports from the recent literature showing predictive value positive estimates

First author	*Year*	*Comment*	*Tumor characteristics*	*No.*	*Predictive value positive (%)*
Baak[4]	1982	Panel of 4 pathologists	Mucinous ovarian tumors	49	76
Cooke[5]	1984	Quality control survey	Mucinous ovarian cancer, low malignant potential	175	70
Hernandez[6]	1984	Panel of 2 pathologists	Ovarian epithelial cancer		
			Histologic type	68	60
			Histologic grade	68	60
Cramer[7]*	1987	Panel of 7 surgical pathologists	Ovarian epithelial and nonepithelial cancer		
			Mucinous	14	43
			Serous	25	32
			Clear cell	15	20
			Endometrioid	30	17

*Predictive value positive for this study is taken as the authors' "unanimity or near-unanimity (at most, one discordant pathologist)" category.

nally, the predictive value positive gives only part of the picture. Whereas all 21 reports of clear cell carcinoma made by the contributing pathologists had the concurrence of the expert panel, the panel members diagnosed 13 other clear cell malignancies that the contributing pathologists did not.

In comparing our results with those reported earlier, we found that each of the reports dealt with a different approach to investigation of the accuracy of cancer diagnosis (see Table IV). In addition, three of them focus more attention on mucinous carcinoma than the analysis reported here. The work of Baak et al.,[4] Hernandez and his colleagues,[6] and Cramer and his coworkers[7] each involved the comparison of individual members of a group of expert pathologists (four, two, and seven experts, respectively). It is important to emphasize that whereas the predictive value positives differ from study to study, differences in study design and clinical information known by the pathologists limit the value of comparing these investigations in detail. The specimens reviewed in the Cancer and Steroid Hormone Study were collected in a 2-year period that ended in December 1982; it is possible that the predictive value positive for the diagnosis of ovarian cancer by pathologists might have improved since that date. The studies cited here all have predictive value positive estimates that are near or less than those reported from the Cancer and Steroid Hormone Study. This suggests that if a change occurred, it was not appreciable; nonetheless, differences in study design limit the value of such a comparison.

The approach taken to validate the diagnosis of primary ovarian cancer in our analysis is more like that used in a study that assessed the diagnosis of lymphomas.[11] Nonetheless, the variability in the diagnoses by pathologists of these hematologic malignancies was substantial, ranging from 52% to 89%. The investigators concluded that variability in the diagnoses by pathologists decreases as an observer's experience increases and that the variability is least among expert pathologists.[11]

The statistical approach in some studies[7] of this problem make use of the κ test. Fleiss[10] points out that the κ statistic is suitable when all those making a set of observations are equally experienced; otherwise, he states, other tests may be more appropriate. Maclure and Willett,[12] in their assessment of 13 papers in which the κ test had been used, point out that it is ". . . a measure of agreement between two observers classifying subjects into two nominal categories. . .." They state that under circumstances like those in this analysis of ovarian cancer, alternative analytic approaches would be more appropriate.

These results from the Cancer and Steroid Hormone Study indicate that primary ovarian cancer is diagnosed with a very high level of predictability in the United States. Nonetheless, cancer that metastasizes to the ovary made up a large proportion of the very small percentage of malignancies that are not correctly diagnosed. For those few patients in whom this occurs, the consequences may be serious because the primary cancer could go untreated. In addition, this analysis indicates that ovarian cancer of low malignant potential is interpreted as invasive malignancy in almost one of every eight cases (57 of 464, or 12%) of primary ovarian cancers, as shown in Table II. To the extent that this leads to treatment that has more frequent or more serious side effects, this problem with diagnosis also influences patients with this disease.

These results lead us to recommend that research on the different histologic types of ovarian cancer be reviewed by a panel of pathologists experienced with the

diagnosis of gynecologic disorders. The analysis of clear cell ovarian cancer supports our concern. Whereas the panel agreed wth the contributing pathologists on all 21 clear cell ovarian cancers, the panel found 13 other instances in which tumors reported as endometrioid were reclassified by the panel as clear cell ovarian cancer, indicating that the histologic type of 38% (13 of 34 clear cell cancers) of malignancies with this cell type was revised as a result of the review.

Guidance for clinical practitioners is more difficult to suggest. Although ovarian cancer that has metastasized to the ovary from some other primary site is rare, the possibility of a distant primary site is the first and most serious factor to be considered in the diagnosis of ovarian cancer. In addition, if treatment will be influenced by the histologic type of primary ovarian cancer, review of such specimens by competent colleagues (even if only one is available) deserves serious consideration.

No matter what role a physician plays in caring for women at risk of ovarian cancer, their survival depends on correct identification of the origin of the malignancy and may be influenced by histologic type as well as by clinical characteristics. For these reasons, the precise diagnosis of ovarian cancer by pathologists is important for researchers, clinicians, and women with this condition.[13]

Spontaneous ovarian-to-vaginal fistula: A case report

Plaul Claman, MD,[a] Mark Dover, MD,[b] Raphael Saginur, MD,[c] Hardy Tao, MD,[d] and Manuel Orizaga, MD[e]

Ottawa, Ontario, Canada

A 59-year-old nulligravid woman presenting with resistant vaginitis was found to have a spontaneous ovarian-to-vaginal fistula arising from a benign ovarian abscess. (Am J Obstet Gynecol 1991;164:71-2.)

Key words: Fistula, ovarian to vaginal

Although ovarian-rectal fistula and intestinal-vaginal fistula have been reported, the occurrence of ovarian-vaginal fistula appears to be a rare event indeed. Previous cases reported involving ovarian-vaginal fistula were after vaginal hysterectomy[1] or in association with a cystic teratoma.[2]

Case report

A nulligravid, 59-year-old woman with type II diabetes presented with a 1-year history of a foul-smelling vaginal discharge that was unresponsive to multiple treatments.

Approximately 1 month before the onset of vaginal discharge, this patient was admitted to another hospital with abdominal pain, leukocytosis, and an ultrasonographic diagnosis of a right-sided pelvic abscess. After 2 weeks of parenteral antibiotics (ampicillin and tobramycin) the pain lessened and the abscess had halved in size on ultrasonographic examination. The patient was discharged home on a regimen of oral antibiotics (cephalexin) with plans to be readmitted 3 months later for interval appendectomy. After hospital discharge (about 2 months before the appendectomy) she began to notice this foul-smelling vaginal discharge. The discharge was copious enough to require the use of up to two dozen vaginal pads daily. An appendectomy neither changed the nature of discharge nor cured the still persistent problem of abdominal pain. Pathologic examination of the appendix showed some periappendiceal inflammation and a small carcinoid tumor of the mucosa and submucosa, which was not considered significant.

Over the ensuing 9 months her family doctor prescribed multiple courses of tetracycline, metronidazole, antifungal cream, and AVC (sulfanilamide, aminacrine, allantoin) cream. Although the vaginal discharge would transiently improve with tetracycline, it returned within days of stopping this medication. Medical history was otherwise unremarkable.

When she was referred to us, we found her to be a moderately obese normotensive woman in no physical distress. Findings of general physical examination were unremarkable except that there was some tenderness to deep palpation in the right lower abdomen. On pelvic examination the vulva was normal although somewhat erythematous. The vagina was also normal with healthy rugations although there was a purulent yellowish foul discharge. Microscopic examination with potassium hydroxide and saline solution preparations were negative for clue cells, yeast, and trichomonas. On careful examination of the vaginal vault there appeared to be a possible fistulous opening at the cervical-vaginal junction at the 7 o'clock position (just medial to the uterosacral ligament insertion area). Because of good uterine support and obesity this fistulous tract could not be clearly seen or cannulated. A computerized tomographic scan of the pelvis demonstrated a thick-walled cystic structure 5 cm in diameter in the right lateral aspect of the pelvis at the level of the inferior portion of the right sacroiliac joint. A percutaneous injection of contrast media through a 22-gauge needle was done under fluoroscopic control, which demonstrated clear evidence of a cavitating space with a small lumen fistula approximately 2.5 cm long that was communicating with the right lateral aspect of the vaginal fornix (Fig. 1). Methylene blue dye was then injected into the abscess cavity and was subsequently found in the vagina on physical examination.

With these data a laparotomy was performed. Findings at operation included minimal adhesions with a normal uterus. Both ovaries and tubes, however, were involved in dense adhesions, with the adnexa bilaterally bound to the lateral pelvic sidewalls. The left ovary in itself was normal. The right ovary, however, was cystically enlarged to approximately 4 cm in diameter and stuck to the vaginal fornix with an apparent fistulous tract. After the ovary was dissected free, there was a definite opening into the vaginal fornix. This was curetted clean and the fistulous opening was closed with a purse-string suture of 2-0 proline. An oophorectomy

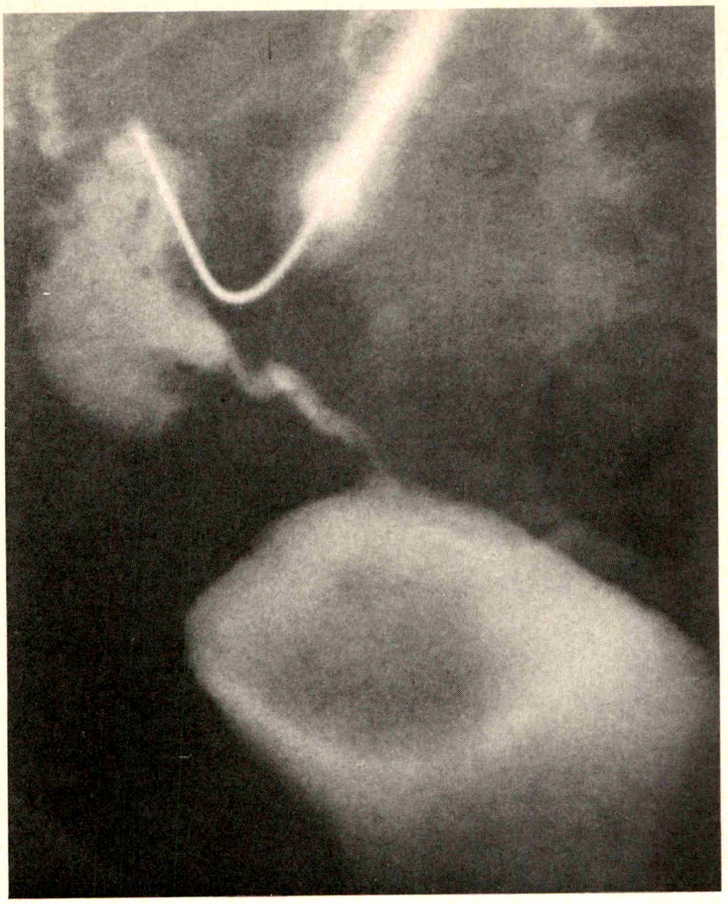

Fig. 1. Fluoroscopically controlled percutaneous injection of contrast media into the abscess cavity. A 3 cm fistula is noted between the cavity and the vaginal fornix. Before removal of the 22-gauge needle, methylene blue dye was injected into the cavity, which was then found in the vaginal vault on physical examination.

was performed. The final histologic diagnosis was consistent with a benign ovarian abscess. After operation the patient noticed immediate resolution of the vaginal discharge. Her recovery was complicated only by a subcutaneous wound infection, which was treated with drainage and antibiotics. Culture of the ovarian abscess did not show significant bacteria, probably because the patient had received preoperative antibiotics (gentamicin, metronidazole, and penicillin).

Comment

This is the first report of a spontaneous ovarian vaginal fistula associated with a benign ovarian abscess that was likely because of chronic pelvic inflammatory disease (as opposed to a complication of surgery or a cystic teratoma). Perhaps this patient's diabetes put her at higher risk for chronic infection with this distinctly unusual entity of ovarian-vaginal fistula, where the ovary, which was adherent to the vaginal fornix, had drained into the vaginal fornix via a fistulous tract.

Relationship of laparoscopic findings to self-report of pelvic pain

Anna L. Stout, PhD,[a] John F. Steege, MD,[b] William C. Dodson, MD,[c] and Claude L. Hughes, MD, PhD[c]

Durham, North Carolina

An assessment battery including standardized measures of behavioral and psychosocial factors associated with other chronic pain conditions was administered to 102 women scheduled for laparoscopic surgery. Surgeons who were blinded to the patient's self-reported pain data completed the American Fertility Society classification for endometriosis and adhesions on the basis of observed physical disease. Although American Fertility Society classification scores were significantly related to self-assignment into pain or no-pain groups, the extent of physical disease evaluated by this procedure was not significantly correlated with ratings of pain levels or a number of indexes of impairment. The group of patients with laparoscopically diagnosed pathologic conditions reported higher pain levels and greater interference than the group who reported pain and had negative laparoscopic results; however, some women with observable pathologic conditions reported no pain symptoms. (AM J OBSTET GYNECOL 1991;164:73-9.)

Key words: Chronic pelvic pain, pain assessment, laparoscopic surgery

The complaint of chronic pelvic pain is one of the most frustrating and controversial areas of gynecologic practice. Although a number of possible organic conditions have been considered as etiologic factors, no physical abnormality can be documented in many women who report chronic pelvic pain. Early reports in the medical literature implied that women who reported chronic pelvic pain had a high degree of emotional disturbance such as feminine identity problems arising from conflicts regarding adult sexuality[1]; psychiatric disturbance characterized by mixed character disorders with predominant schizoid features[2]; and high neuroticism and unsatisfactory relationships.[3] Duncan and Taylor[4] and Benson et al.[5] reported an association between the onset of symptoms of pelvic pain and emotional stress.

These earlier published reports of the presence of pelvic pain symptoms in the absence of clear organic disease have been questioned from several perspectives. Because physical abnormalities that cannot be identified on pelvic examination can often be observed during laparoscopic surgery, the women who were considered to have normal pelvic examinations may have had some type of organic pathologic condition if evaluated by current procedures. Cundnan et al.[6] reported findings on nearly 1200 patients during diagnostic laparoscopy for pelvic pain. In their series, 63% of the women with normal pelvic examinations before diagnostic laparoscopy had abnormal findings on diagnostic laparoscopy. On the other hand, questions have been raised with regard to the assumption of a cause-and-effect relationship between physical findings and pain symptoms. Kresch et al.[7] identified some possible pathologic condition in 29% of asymptomatic women who underwent laparoscopic surgery for tubal ligation.

Other methodologic criticisms that raised questions with regard to the conclusions from previous studies suggesting the high prevalence of psychopathology in chronic pelvic pain patients are as follows: (1) selection bias in the sample of patients who were studied psychologically because of high refusal rates for psychological assessment that are reported in some studies; (2) potential bias of psychological evaluators who were not blinded to the presence or absence of identified organic disease; and (3) lack of appropriate control groups to establish population base rate data for problems such as sexual adjustment difficulties. In all studies of which we are aware, limited information is available on the psychological status of these women before pain onset. Several more recent investigations[8-10] reported that women who had pelvic pain with positive laparoscopy findings and negative laparoscopic findings

exhibited similar psychological profiles, raising the question of whether pain experience itself produces the emotional and sexual difficulties associated with chronic pelvic pain.

Current conceptualizations of chronic pain emphasize the complexity of the chronic pain condition. The pain experience appears to be a product of more than tissue disease. Behavioral and psychological factors are increasingly recognized as important contributors to the understanding and treatment of chronic pain syndromes. The conditions of chronic back pain and chronic headache pain have been the most extensively studied. Variables such as limitation of activities, ratings of pain severity, pain descriptions, administration of medication, and perception of control have been shown in numerous studies to predict functional disability and response to medical treatment often to a greater extent than organic pathologic factors identified in these conditions.

The two most common physical abnormalities that are suspected in the organic cause of chronic pelvic pain are endometriosis and adhesions. The extent to which endometriosis and adhesions can account for chronic pelvic pain remains controversial. As previously cited, Kresch et al.[7] discovered endometriosis or adhesions in 29% of asymptomatic women during laparoscopic surgery for tubal ligation. Rapkin[11] found laparoscopically diagnosed evidence of pelvic adhesions in 26% of patients with chronic pain and 39% of infertility patients; however, only a very small portion of the infertility patients with pelvic adhesions complained of pelvic pain. In clinical practice, many gynecologists have reportedly observed patients with a few small endometriosis implants or adhesions who report significant pain, whereas other patients who are found to have significant disease may not describe pain symptoms.

In their review of behavior assessment and treatment of chronic pain, Keefe and Gil[12] offer several suggestions for future assessment research including recommendations for the use of standardized assessment of behavioral and psychosocial factors and standardized methods for quantification of the severity of the tissue disease basis for pain. The purpose of this preliminary investigation is to explore the relationship between findings of endometriosis and adhesions documented by laparoscopic surgery with a standardized structured classification system and the self-report of pain parameters on selected standardized psychological instruments. Information from this study will be used to guide the direction of future research. More specifically, if organic status is found to be highly correlated with pain behavior and functional status, medical-surgical approaches to organic pathologic conditions would appear to be the most effective treatment. However, if impairment cannot be accounted for on the basis of organic pathologic findings identified by the currently accepted medical diagnostic procedures, further systematic evaluation of psychosocial factors seems clearly mandated.

Material and method

Subjects. The subjects were 102 women scheduled for laparoscopic surgery for diagnostic or treatment purposes by gynecologists on the faculty of Duke University Medical Center. Subjects were recruited from the Division of Reproductive Endocrinology and Division of Gynecology of the Department of Obstetrics and Gynecology. A screening questionnaire inquired with regard to demographic variables, marital satisfaction, gynecologic concerns, reason for laparoscopy, and the presence or absence of dysmenorrhea, pelvic pain other than during menses, and dyspareunia. Indications for having laparoscopic surgery were as follows: to investigate causes of pain, 64%; to investigate causes of infertility, 35%; to investigate abnormal findings from other examinations or tests (pelvic examinations, sonograms), 19%; and for sterilization only, 15%. With the exception of the sterilization group, some subjects were undergoing laparoscopic surgery for more than one reason.

Procedures. Approval for the study was obtained from the Institutional Review Board before initiation of the protocol. Subjects scheduled for laparoscopy were identified from the operating room schedule and arrangements were made to contact the subjects about participation in the study at the time of preoperative evaluation. Informed consent was obtained at that time. Subjects completed and returned the questionnaires before the laparoscopic surgery and before operative physical findings were discussed to eliminate the influence of physical findings on their responses.

The surgeons of the patients who agreed to participate in the study were asked to complete the American Fertility Society classification for endometriosis and adhesions[13] with clarification to score for the presence of adhesive disease regardless of presumed cause. The only exception to the scoring rules was that scores for pathologic conditions in a remaining adnexal area were not doubled if the other ovary or tube were absent because this weighting procedure seemed specifically related to fertility rather than to currently observed pathologic conditions. Surgeons were also asked to record and diagram on the American Fertility Society scoring form any other evidence of abnormality. These forms were then also scored by one of the authors (J.F.S.) for the presence or absence of disease to exclude the existence of pathologic conditions other than endometriosis or adhesions. Surgeons were blinded to the patient's self-reported questionnaire data related to pain symptoms.

Measures. Because this is an exploratory study of the relationship between self-report of chronic pelvic pain and physical findings, a battery of assessment measures was assembled that included some standardized evaluation instruments that have been used with other chronic pain populations and some original questionnaires were developed to assess specific characteristics of pelvic pain. The assessment battery included the following:

Pain Questionnaire for Women. The Pain Questionnaire for Women (Stout, unpublished data) is a pilot questionnaire designed to evaluate characteristics of pelvic pain including a diagram of the female torso for shading in pain location, questions related to reported symptoms of endometriosis and adhesions, association with the menstrual cycle and sexual activity, and questions regarding pain parameters, medication taken, and physical activity.

McGill Pain Questionnaire—Pain Rating Index. The McGill Pain Questionnaire[14] is a well-established and commonly used instrument with adequate psychometric properties. The rationale for the development of the McGill Pain Questionnaire has its basis in the gate control theory of pain.[15, 16] The gate control theory postulates that pain is a multidimensional concept with sensory, motivational and evaluative components. The Pain Rating Index of the McGill Pain Questionnaire is frequently extracted for use in the evaluation of pain and to track response to pain control interventions. The Pain Rating Index currently includes 20 adjective subclasses of two to six pain descriptions ranked according to intensity of pain. The values of the words chosen by a patient are then added to obtain a score for each of the following categories: sensory, affective, evaluative, miscellaneous, and a total score for all categories. In accordance with Pain Rating Index instructions, patients are not required to select a word from every subclass and are limited to choosing the one-word "best descriptor" in each subclass. The total number of words chosen was also calculated from the Pain Rating Index.

West Haven–Yale Multidimensional Pain Inventory, part I. The West Haven–Yale Multidimensional Pain Inventory[17] is a brief, psychometrically sound inventory designed to provide an evaluation of several aspects of a person's unique subjective experience of pain. Part I consists of six scales that were developed a priori to assess the following areas: (1) pain severity and suffering; (2) pain-related life interference including interference with family and marital functioning, work and work-related activities, and social-recreational activities; (3) dissatisfaction with present level of functioning in each of the subareas listed in area 2; (4) appraisal of support received from spouse, family, and significant others; (5) perceived life control, incorporating the perceived ability to solve problems and feelings of personal mastery; and (6) affective distress. Responses to each item are recorded on a seven-point scale ranging from 0 (no change) to 6 (extreme change).

Statistical analysis. Group comparisons for continuous variables were done with the Student t test or Wilcoxon two-sample test where appropriate. Spearman rank correlations were used to assess the relationship between self-reported pain variables, physical findings, and age. Because the Spearman rank correlation test does not adjust for weighted scores and it is unknown whether the weighting procedures for pathologic conditions in the American Fertility Society scoring system are relevant for pain symptoms, American Fertility Society total scores were collapsed to a 0 to 6 scale to match the range of other variables. This modified American Fertility Society total score was created by setting up a gradient of six levels of physical pathologic conditions on the basis of distribution of American Fertility Society total scores. Group differences for categoric variables were done with the χ^2 test, adjusting for inadequate cell sizes when appropriate.

Results

Pain versus no pain group. Of the 102 women who participated in the study, 88% reported on the screening questionnaire that they had some type of pelvic pain (dysmenorrhea, 90%; pain at other times during the menstrual cycle, 82%; and dyspareunia, 77%). The group of women who were self-assigned to the pain group ($N = 90$) were compared with the group who did not experience pelvic pain, no-pain group ($N = 12$) (Table I). There were no significant differences between the two groups with regard to age (both 32 ± 6 years), race, education, full-time employment, marital status, or global rating of marital satisfaction. In addition, no significant differences were found between the pain and no-pain groups in the number of previous surgeries, history of abdominal or pelvic surgery, motivation for laparoscopic surgery to investigate infertility, or the current or future desire for pregnancy. As might be expected, patients in the pain group indicated more frequently that investigation of pain, abnormal examination findings, or concern about endometriosis, adhesions, or sexually transmitted diseases were the motivations for the laparoscopic surgery.

The pain and no-pain groups were significantly different with regard to total American Fertility Society scores ($p \leq 0.004$). The pain and no pain groups were also significantly different with regard to the modified American Fertility Society total scores ($p \leq 0.01$), indicating the total scores on the American Fertility Society classification of endometriosis and adhesions were significantly related to patient's self-assignment into the pain or no-pain group. There was also a trend for endometriosis ($p \leq 0.09$) and adhesions ($p \leq 0.19$) to be

Table I. Comparison of self-reported pain group with no-pain group

	Pain (N = 90)	*No pain (N = 12)*
Age (yr)	32.2 ± 6.2	32.1 ± 6.0
No. of previous surgeries	1.2 ± 1.3	0.8 ± 1.2
American Fertility Society total score	7.2 ± 12.5*	1.6 ± 4.6*
Modified American Fertility Society score	2.2 ± 2.1*	0.7 ± 1.4*
White (%)	88	67
College grad (%)	36	42
Employed full-time (%)	78	83
Married (%)	74	67
Satisfied with marriage (%)	61	63
Having children (%)	47	75

Concern about sexually transmitted disease (%)	34*	8*
Concern about endometriosis (%)	62*	25*
Concern about adhesions (%)	52*	17*
Past abdominal or pelvic surgery (%)	56	42
Investigating infertility (%)	34	50
Investigating pain (%)	72*	0*
Investigating examinations/tests (%)	21*	0*

*$p < 0.05$.

documented more frequently in the pain group, but differences were not statistically significant.

Further analysis of information from the battery of questionnaires is limited to the pain group because women who did not report pelvic pain did not complete these instruments. Within the pain group, the relationship was explored between the modified American Fertility Society total score and a number of pain variables considered important in assessment of the impact of pain symptoms on the ability to function. The extent of physical disease classified by the modified American Fertility Society score was not significantly correlated with duration of the pain symptom, rated levels of dysmenorrhea, luteal or follicular phase pain, dyspareunia, pain frequency, duration of pain episodes, days in bed, or medication taken. McGill Pain Rating Index sensory, affective, evaluative, and miscellaneous subscale scores and McGill Pain Rating Index total scores were not significantly correlated with American Fertility Society scores of physical findings. The relationships between the extent of physical disease and areas assessed by part I of the West Haven–Yale Multidimensional Pain Inventory were also examined. The amount of physical disease observed at laparoscopy was not significantly correlated with Multidimensional Pain Inventory subscale scores of pain severity, interference, life control, affective distress, or support.

Table II. Diagnostic laparoscopy findings and self-reported pelvic pain symptoms

Physical pathologic condition	*Self-reported pain*		
	Present	*Absent*	*Total*
Present	71	7	78
Absent	19	5	24
TOTAL	90	12	102

The association of self-reported pain descriptions with physical findings observed during laparoscopy was also examined. The report of rectal, bladder, or radiating leg pain was not related to the findings of endometriosis in this sample, although the report of menstrual cycle variation of pain symptoms was marginally related to a finding of endometriosis ($p < 0.12$). The report of rectal or bladder pain was also not related to the finding of adhesions; however, radiating leg pain ($p < 0.15$) and menstrual cycle variations ($p < 0.13$) in pain showed a tendency to contraindicate adhesions. No association was found between the documentation of endometriosis or adhesions with pain worsened by bending, lifting, physical exercise, reaching, sitting, standing, lying down, walking, or bladder or bowel elimination.

Pathologic finding versus no pathologic finding. Findings of laparoscopic surgery were categorized into those with physical pathologic conditions and those with no physical pathologic conditions by a gynecologist blinded to the self-reported pain ratings and classified for location of disease into seven categories of the pelvic region as follows: right, left, central, bilateral, diffuse, right and central, and left and central. The boundary between unilateral and central areas was arbitrarily drawn between the umbilicus and approximately the medial aspect of the femoral canal. Of the 102 patients in this sample, 78 (76%) were considered to have some type of pathologic condition and 24 (24%) were considered to have negative laparoscopic findings. Nineteen of the 24 patients with negative laparoscopic findings reported pelvic pain symptoms (Table II). Further statistical comparisons were then made between the group with self-reported pain symptoms and negative laparoscopic findings ($N = 19$) and the group with self-

Table III. Comparison of group with pathologic condition present and group with absence of pathologic condition in patients with pain

	Range of possible scores	*Pathologic condition*	
		Present (N = 71)	*Absent (N = 19)*

MPI, Multidimensional Pain Inventory.

reported pain symptoms and positive laparoscopic findings ($N = 71$) (Table III). The group with laparoscopically diagnosed pathologic conditions had significantly higher rated levels of dysmenorrhea ($p \leq 0.04$) and follicular phase pain ($p \leq 0.02$), more time in bed ($p \leq 0.003$), higher scores on the McGill evaluative subscale ($p \leq 0.04$), and Multidimensional Pain Inventory pain severity ($p \leq 0.003$) and interference subscales ($p \leq 0.0001$). No other differences emerged between the two groups in their global assessment of the quality of marital relationship or any other variables assessed in this study.

The group ($N = 7$) with pathologic conditions identified at laparoscopy but who reported no pain symptoms was too small for statistical analysis but was of particular interest. American Fertility Society total scores in that group ranged from 0 to 16. Described pathologic findings included 10-week size fibroids ($N = 1$), minimal endometriosis ($N = 3$), and filmy and dense adhesions ($N = 3$).

The location of pathologic conditions observed during laparoscopic surgery was also compared with the location of pain indicated on the body maps of the female torso. With the seven categories of the pelvic region described in this article, there was an exact match between location of pathologic condition from laparoscopic surgery and self-reported location of pain in 25%; however, the self-reported pain location was completely outside the area of pathologic findings in only 3% of the cases. The remainder of the cases (72%) shaded in an area on the body map larger than the area of pathologic findings or had an area of disease larger than the indicated pain area. Five of the 19 women who reported pain but who did not have an identified pathologic condition described very diffuse pain.

Comment

Patients were included in this study if they indicated that they considered themselves to have pain during menstrual bleeding, in their pelvic or abdominal areas at other times during the menstrual cycle, or during sexual intercourse. Data were examined to determine whether women might qualify for the study on the basis of mild-moderate dysmenorrhea that other women might consider normal; however, no patients were included in the pain group who only reported dysmenorrhea at a level of ≤3 on a 0 to 6 scale. Nevertheless,

the broad inclusion criteria may have weakened relationships with more severe reports of pain. The present study is limited by the small number of patients without any pain symptoms; however, laparoscopic surgery is unlikely to be performed unless some suspicion of abnormality exists or for the purpose of sterilization. Whereas the present study does not represent a cross-section of the adult female population, it does use a prospective design feature of quantification of self-reported pelvic pain before laparoscopic inspection for diagnostic evaluation. Furthermore, because the operating surgeons were unaware of the pain questionnaire responses, observer bias should be minimized by the design.

Although physical pathologic conditions may produce sensory changes that many women label as pain, this study strongly suggests that the degree of pelvic organic disease as evaluated by the currently accepted diagnostic procedure (diagnostic laparoscopy) is at most minimally related to rated levels of pain symptoms and functional impairment. On the basis of these findings, the majority of women reporting pelvic pain symptoms may be expected to have some type of physical abnormality, primarily endometriosis or adhesions, observed during laparoscopic examination. The location of the abnormality almost always corresponds to the location of the pain. However, the contribution of these physical conditions to the pain may be relatively small in comparison with multiple other less easily assessed psychosocial factors. Within a group of women who reported pelvic pain, a significant portion (21% in this sample) showed no evidence of physical disease at laparoscopy. A few women in this sample who underwent laparoscopic surgery for reasons other than investigation of pain had comparable physical findings that were not associated with pain symptoms.

The minimal relationship between physical findings and severity of self-reported pain symptoms appears to suggest two possible explanations. The first might be that the American Fertility Society classification for endometriosis and adhesions is not applicable to the type of pathologic condition associated with pelvic pain; however, the feasibility of this explanation is certainly reduced by the fact that 19 of the 24 patients with negative laparoscopic findings on the American Fertility Society system were also not considered to have any abnormal pelvic findings (including other possible pathologic conditions) when reviewed by a gynecologist who was blinded to the patients' pain ratings. It is possible that these patients may have physical discomfort on the basis of some type of functional rather than anatomic process (i.e., prostaglandins), which cannot be identified by laparoscopic examination. Nevertheless, this group with normal laparoscopic findings who reported pain symptoms may be reduced as more sensitive medical or surgical diagnostic techniques are developed. Further exploration of methods for quantification of the severity of pelvic disease is planned.

Second, the evidence from this data strongly suggests marked individual differences in how persons experience or interpret physical sensory input from pelvic anatomy. Although the subsamples were too small for statistical analysis in this study, the two discordant subgroups (pain present—pathologic condition absent, pain absent—pathologic condition present) would be an interesting focus for future studies.

In other chronic pain conditions, psychological factors have been shown to account for a significant portion of these individual differences in functional impairment. Keefe et al.[18] found that depression was a significant predictor of pain behavior in patients with low back pain independent of demographic or medical status variables; however, psychological variables (depression, anxiety, and helplessness) were not found to be independent predictors of pain behaviors in rheumatoid arthritis patients[19] pointing out the danger of generalizing from one chronic pain condition to another. Depression evaluated by the affective distress subscale of the Multidimensional Pain Inventory was not a significant predictor of functional impairment in this sample; however, a possible relationship may have been obscured because the majority of women without pain symptoms were undergoing laparoscopic surgery for investigation of infertility and may also have been experiencing comparable depressive symptoms. Because patients without pain symptoms did not complete the Multidimensional Pain Inventory, this hypothesis cannot be evaluated from this data. Stout et al.[20] presented preliminary evidence that patients with pelvic pain may differ from other groups of women with chronic pain conditions on several psychosocial and behavioral variables. While awaiting the results of further research to delineate the impact of psychosocial factors on pelvic pain symptoms, clinical results may be improved by simultaneously restoring normal anatomy to the degree possible and administering or recommending therapeutic attention for emotional and psychosocial concerns.

We express appreciation to gynecologists on the faculty of Duke University Medical Center for allowing access to their patients for this study and for their time in completing the American Fertility Society scoring system at laparoscopic surgery.

Phosphorus 31 magnetic resonance spectroscopy of human placenta and quantitation with perchloric acid extracts

Helen H. Kay, MD,[a, c] John D. Gordon, MD, Anthony A. Ribeiro, PhD,[c] and Leonard D. Spicer, PhD[b, c]

Durham, North Carolina

Phosphorus 31 magnetic resonance spectroscopic studies of fresh placental tissue are reported that indicate resonances for adenosine triphosphate, inorganic phosphate, sugar phosphates—phosphomonoesters, and phosphodiesters. Perchloric acid extract methods were used to further characterize and quantitate phosphorous metabolites in term human placentas by phosphorus 31 magnetic resonance spectroscopy. The perchloric acid extracts give enhanced resolution of phosphorus signals and allow identification of other phosphorus metabolites including small amounts of phosphocreatine. Emphasis was placed on quantitating adenosine triphosphate levels in the acid extracts with the use of the external reference standard hexachlorocyclotriphosphazene in a coaxial capillary system. Adenosine triphosphate levels measured in this way ranged from 0.404 to 0.709 μmol per gram wet weight. Comparison with an internal standard method with phosphocreatine is also reported. Contribution to the measured high-energy phosphate pool from blood in the highly vascularized tissue was found to be relatively large and could range from 30% to 50% of the total adenosine triphosphate measured. (AM J OBSTET GYNECOL 1991;164:80-7.)

Key words: Phosphorus 31 nuclear magnetic resonance spectroscopy, human placenta, adenosine triphosphate

Nuclear magnetic resonance spectroscopy is a technique that chemists have used to study chemical structure. More recently it has been used to characterize the behavior of molecules in biologic tissue.[1] Magnetic resonance spectroscopy uses the resonant frequencies of certain naturally occurring, nonradioactive nuclei (hydrogen 1, phosphorus 31, carbon 13) that resonate under the influence of an external magnetic field. The exact resonance frequency of the nuclear spin of an atom (e.g., ^{31}P) will depend on the magnetic environment set up by local electrons. This property, termed the chemical shift, allows the nucleus being studied to be identified within a molecule in a chemical solution or in a biologic tissue. The collection of resonance signals at their separate chemical shifts constitutes the magnetic resonance spectrum. The units of chemical frequency shift in the spectra are parts per million (ppm) or hertz.

The ability of magnetic resonance spectroscopy to monitor the atomic signals of molecules makes it an important tool for metabolic studies in a variety of organ systems in both human beings and animals.[2] Because it is considered a noninvasive procedure magnetic resonance spectroscopy may ultimately also become a very useful clinical tool. Magnetic resonance spectroscopy has recently been used in preliminary studies of the human placenta[3, 4] with promising results, suggesting that a better understanding of placental metabolism can be obtained with this technique.

Placental metabolism and function have been generally understudied even though the placenta plays an important role in the maintenance of fetal well being. Its primary functions are to transport nutrients (e.g., oxygen, amino acids, sugars, and lipids) to the fetus and to remove waste from the fetus. Another major function is synthesis of large amounts of steroid hormones, primarily estrogen and progesterone. Estrogens stimulate placental uptake and use of glucose as well as formation of glycogen and glycerol.[5] The placenta also actively synthesizes large amounts of proteins such as human chorionic gonadotropin and human placental lactogen, compounds that maintain maternal production of steroid hormones and regulate use of fetal glucose much like human growth hormone.[6] Finally, the placenta produces large amounts of lactate that is used by the fetus for gluconeogenesis.[7] Alterations in any of these and other placental functions may

lead to a compromised fetus such as a growth-retarded fetus.

As an initial step toward the study of placental metabolism by nuclear magnetic resonance spectroscopic methods, we used perchloric acid extract methods to characterize the phosphorus metabolites in term human placentas by ^{31}P magnetic resonance spectroscopy. In the studies described in this article we focused on the high-energy phosphate signals from the nucleoside triphosphates, in particular adenosine triphosphate. Alterations in the adenosine triphosphate levels and other adenosine nucleotides may be associated with pathologic conditions such as preeclampsia.[8, 9] In addition, high levels of placental adenosine triphosphate have been associated with high glucose levels in vitro[10] and may play a role in diabetic pregnancies, which often result in abnormally large infants. Lastly, ion transport, an important process in the placenta, is thought to be adenosine triphosphate–dependent because the addition of ouabain, an inhibitor of adenine triphosphatase, has been shown to affect such transport.[11] Therefore, abnormalities in placental metabolism may be shown by altered levels of adenosine triphosphate. Here we report results of our current efforts in the development of quantitation methods for adenosine triphosphate resonances in fresh and frozen human placental samples so that ultimately comparisons can be made between normal and abnormal placentas that may lend further insights into pregnancies that result in abnormal outcomes.

Material and methods

Fresh tissue preparation. Freshly delivered placental tissue from both vaginal and cesarean section births were studied. Approximately 5 gm of tissue was sharply dissected free from the remainder of the placenta and placed into a 20 mm nuclear magnetic resonance tube within 1 minute of delivery and maintained on ice for no more than 1 hour before spectra were acquired. Spectra were obtained with a 65° flip angle (40 μsec), an acquisition period of 1.12 seconds, a relaxation delay of 1 second (total pulse interval 2.12 seconds), and 256 acquisitions. These conditions were used to qualitatively assess ^{31}P spectral features and correspond to partially saturated inorganic phosphate resonances but to fully relaxed adenosine triphosphate signals inasmuch as the measured longitudinal (T1) relaxation value that determines the degree of relaxation for adenosine triphosphate in the tissue at 300 MHz field strength is 0.5 to 0.6 sec.

Tissue extracts. Perchloric acid extracts of placental tissue were prepared with a modification of a previously described technique.[12] Placentas were harvested by removing small pieces of tissue from the maternal side and freezing them in liquid nitrogen within 1 minute of delivery. Tissue trauma was minimized by use of sharp dissecting instruments, by removal of each piece with minimal dissection, and by performance of the dissection with the placenta remaining in the dissecting pan. The frozen tissue was pulverized in a custom-designed stainless steel mortar and pestle chilled with liquid nitrogen. A 20 gm sample of the finely ground tissue was mixed with 20 ml of 1 mol/L perchloric acid that had been precooled to the temperature of dry ice. The perchloric acid–tissue mixture was allowed to warm to −10° C in the ambient air for 15 minutes during which time the metabolites were extracted. It was then centrifuged at 40,000 rpm at −4° C for 20 minutes to separate the remaining solid fraction. The supernatant containing the extracted metabolites was decanted into a chilled beaker and neutralized to just above pH 7.0 through the dropwise addition of potassium hydroxide. The potassium perchlorate precipitated during neutralization was removed by a second centrifugation step identical to the first, and the supernatant was then passed over a chelating resin (Sigma Chemical Co., St. Louis) to remove divalent cations. The extract was again titrated to neutral pH with dilute perchloric acid, frozen in a vacuum flask (Virtis Co., Gardiner, N.Y.), and lyophilized to dryness. The extract was then resuspended in 5 ml of 40% deuterated water. For quantitation of spectra, the extracts were placed in the outer chamber of a coaxial 10 mm nuclear magnetic resonance tube with an external reference standard of 25 mmol/L hexachlorocyclotriphosphazene (Aldrich Chemical Inc., Milwaukee)[13] in the inner chamber. These spectra were obtained with a 70° pulse angle (21 μsec), an acquisition period of 1.12 seconds, a relaxation delay of 15 seconds (total pulse interval 16.12 seconds) and 160 acquisitions. These conditions yield fully relaxed adenosine triphosphate signals from the extract, inasmuch as the T1 relaxation time was measured to be approximately 1.8 seconds for the adenosine triphosphate signals of the extract.

Contribution from blood. To determine the contribution of blood to the tissue extract, we performed perchloric acid extracts of maternal blood (peripheral) and fetal blood (cord) from one patient. Perchloric acid (1 mol/L) was added in a 1:1 ratio to 20 ml blood and extracted according to the above protocol.

Nuclear magnetic resonance instrumentation. All spectra were obtained on a spectrometer (model GN-300WB General Electric, Fremont, Calif.) interfaced with a wide-bore superconducting magnet (89 mm bore, 7.0 tesla field) in the Duke Magnetic Resonance Spectroscopy Center. A standard 20 mm broad band probe (General Electric) tuned to 121.4 MHz was used for ^{31}P spectroscopy. The 90° pulses were: 56 μsec for a 20 mm tube with placental tissue; 27 μsec for a

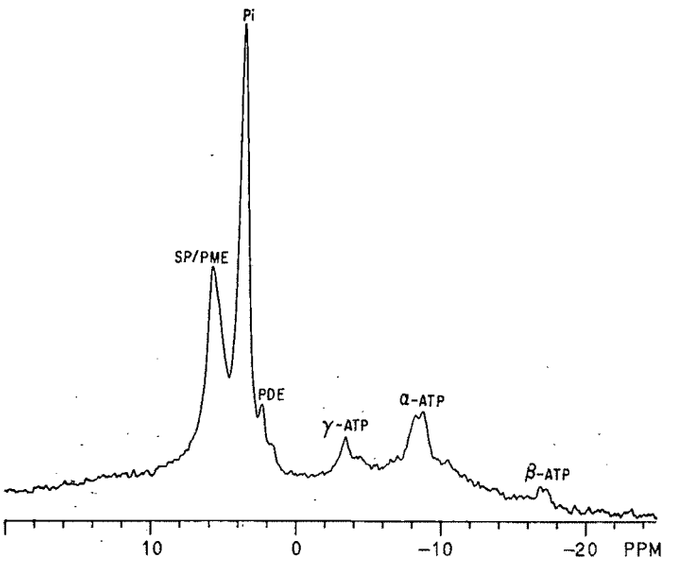

Fig. 1. 121 MHz ^{31}P magnetic resonance spectroscopy spectrum of gross placental tissue. Peaks identified are sugar phosphate–phosphomonoester, *SP/PME;* inorganic phosphate, *Pi;* phosphodiester, *PDE;* α-, β-, and γ-adenosine triphosphate. Spectrum obtained with 65° flip angle (40 μsec), acquisition period of 1.12 seconds, relaxation delay of 1 second (total pulse interval, 2.12 seconds), and 256 acquisitions.

10 mm tube with hexachlorocyclotriphosphazene–extract; 25 μsec for a 10 mm tube with hexachlorocyclotriphosphazene–adenosine triphosphate. Spectroscopic data were collected at the ambient operating probe temperature (approximately 22° C) without temperature regulation. To avoid radio frequency heating effects on the tissue and extracts, no proton decoupling was used. ^{31}P chemical shifts are referenced to phosphocreatine at 0.00 ppm.

External reference standard. Quantitation of adenosine triphosphate levels in the perchloric acid extracts was performed with the external reference standard of hexachlorocyclotriphosphazene and chromium acetylacetonate (Aldrich Chemical Inc.) in a coaxial capillary system.[13] Hexachlorocyclotriphosphazene has proved to be a useful ^{31}P chemical shift reference because its ^{31}P signal (approximately 24.4 ppm at our conditions) exhibits only a small shift with temperature (0.34 ppm between 8° and 50° C) and the narrow hexachlorocyclotriphosphazene signal is easily observed without proton decoupling. The T1 relaxation time of 25 mmol/L hexachlorocyclotriphosphazene in deuterated benzene at 121 MHz was 15 seconds. Addition of 31 mmol/L chromium acetylacetonate reduced the relaxation time for the hexachlorocyclotriphosphazene resonance to <200 msec. A calibration curve was constructed by recording nuclear magnetic resonance spectra for the two-compartment coaxial 10 mm nuclear magnetic resonance tube with 25 mmol/L hexachlorocyclotriphosphazene with 31 mmol/L chromium acetylacetonate in the inner chamber of a 10 mm coaxial insert and varying adenosine triphosphate (Sigma Chemical Inc., St. Louis) concentrations in the outer chamber. Spectra were acquired under identical conditions to those for the perchloric acid extracts. Peak area integration of the fully relaxed adenosine triphosphate and hexachlorocyclotriphosphazene signals generated the calibration curves. The ordinate is presented as the ratio of the area of the β-adenosine triphosphate resonance to that of hexachlorocyclotriphosphazene, whereas the abscissa represents the adenosine triphosphate concentration. This calibration curve gives a quantitative estimate of the concentrations of the various metabolites in the perchloric acid extracts. It is also used to estimate concentrations from peak areas in intact placental tissue although it must be recognized the signal attributed to β-adenosine triphosphate in the typical spectrum of whole tissue may include small contributions from other nucleoside triphosphates.[14] All adenosine triphosphate concentrations reported in this work are expressed as micromoles per gram of wet weight placental tissue.

Internal reference standard. To assess the reliability of quantitation with the external reference standard in our coaxial nuclear magnetic resonance tube, we compared results with those obtained by an internal standard. Because our spectra show at most very small signals from phosphocreatine in placental extracts, we chose to use it as the internal reference standard by spiking our perchloric acid extracts in a fixed volume

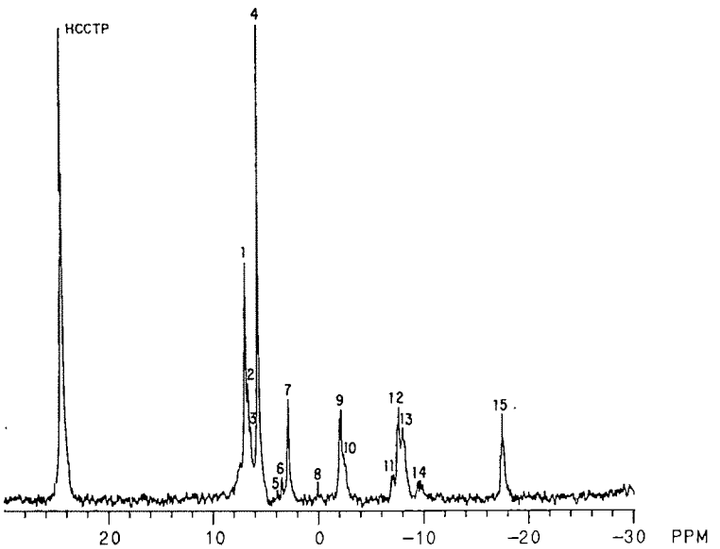

Fig. 2. 121 MHz ^{31}P magnetic resonance spectroscopy spectrum of perchloric acid extract of human placental tissue. Spectrum acquired with 70° flip angle (21 μsec), acquisition period of 1.12 seconds, relaxation delay of 15 seconds (total pulse interval, 16.12 seconds), and 160 acquisitions. Tentative peak assignments on the basis of literature: *1*, sugar phosphates, *2*, 2,3-diphosphoglycerate; *3*, phosphorylcholine; *4*, inorganic phosphate; *5*, glycerophosphorylserine; *6*, glycerophosphorylethanolamine; *7*, glycerophosphorylcholine; *8*, phosphocreatine; *9*, α-adenosine triphosphate; *10*, β-adenosine diphosphate; *11*, α-adenosine diphosphate; *12*, α-adenosine triphosphate; *13*, the oxidized form of nicotinamide-adenine dinucleotide; *14*, uridinediphosphate glucose; *15*, β-adenosine triphosphate. External reference standard, hexachlorocyclotriphosphazene, is at approximately 24.4 ppm with phosphocreatine at zero.

with a standard aliquot of 5 mmol phosphocreatine. Adenosine triphosphate concentrations were then calculated by comparison of the integrated peak areas with that of the added phosphocreatine.

Statistics. A linear regression analysis and a Pearson's correlation coefficient determination was performed to correlate the adenosine triphosphate levels determined with the use of the external reference standard with that found by the internal spiking method.

Results

A typical spectrum obtained from our preliminary studies of fresh placental tissue is shown in Fig. 1. The α-, β-, and γ-nucleoside triphosphates peaks are seen with the largest contributions to these resonances coming from adenosine triphosphate.[14] There is a large inorganic phosphorus peak, and significant resonances corresponding to phosphodiesters and to a sugar phosphate–phosphomonoester envelope. No identifiable resonance from phosphocreatine is observed in this spectrum, a result similar to that reported previously.[3]

Further spectral resolution of components in placental tissue is revealed in the corresponding spectrum of a perchloric acid placental extract in coaxial configuration with the external hexachlorocyclotriphosphazene reference standard as illustrated in Fig. 2. Resonances from specific phosphomonoesters and phosphodiesters such as 2,3-diphosphoglycerate, phosphorylcholine, serine phosphorylethanolamine, glycerophosphorylethanolamine, and glycerophosphorylcholine are clearly distinguishable. Peak assignments are made on the basis of previously reported identification of these compounds.[14] Even with the significantly higher signal/noise ratio and better resolution available in the extracts, only a small peak corresponding to phosphocreatine at 0.00 ppm is observed. Hexachlorocyclotriphosphazene appears as a single line at approximately 24.4 ppm downfield from the phosphocreatine position (0.00 ppm).

The calibration curve relating concentrations to relative nuclear magnetic resonance intensities determined for quantitating these studies is shown in Fig. 3. These data were obtained with commercially available adenosine triphosphate and hexachlorocyclotriphosphazene in a coaxial configuration identical to that used to study the placental extracts. Adenosine triphosphate concentrations from 11 human placentas were determined with both the external hexachlorocyclotriphosphazene standard and the internal spiking with added phosphocreatine. The measured values are listed in Table I and range from 0.404 to 0.709 μmol per gram.

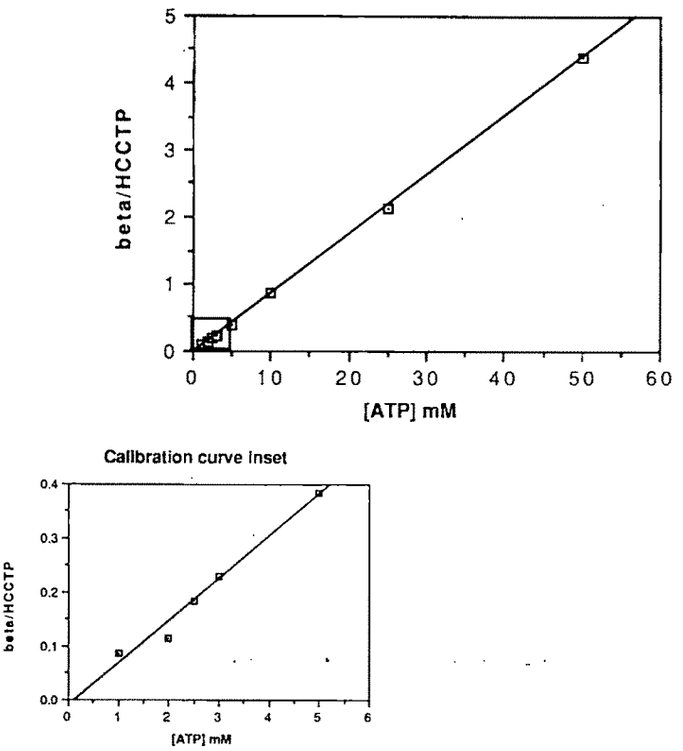

Fig. 3. Calibration curve for use of external reference standard with constant concentration of hexachlorocyclotriphosphazene and varying concentrations of adenosine triphosphate. *Inset* is adenosine triphosphate at lower concentrations.

The correlation coefficient of comparisons between the two methods is 0.755.

Fig. 4 shows a ^{31}P spectrum from maternal blood. The spectrum from fetal cord blood is essentially identical. The significant peaks are those from adenosine triphosphate, 2,3-diphosphoglycerate, and inorganic phosphate. The adenosine triphosphate calculated from the maternal peripheral blood is 0.256 μmol per milliliter blood. Because each gram of placenta represents roughly 1 ml in volume, the adenosine triphosphate contribution from blood in this placenta can be estimated to be approximately 0.205 μmol per gram tissue, assuming that approximately 80% of the placenta is composed of blood (maternal and fetal).[15] This result suggests that blood with this concentration of adenosine triphosphate may actually account for as much as 30% to 50% of the total adenosine triphosphate seen in the tissue extracts and presumably a similar contribution would be observed in in vivo or ex vivo spectra of whole placental tissue.

Comment

Although magnetic resonance spectroscopy has been applied to other tissues and tissue extracts, its use is only beginning to be explored for studies of tissue in the female reproductive tract. Earlier work by Noyszewski et al.[3] has focused on ^{31}P spectroscopy of gross placental tissue that showed resonances for sugar phosphate or phosphomonoester, inorganic phosphate, and adenosine triphosphate but no visible phosphocreatine. Before our systematic efforts at more detailed characterization and quantitation of metabolites, we also examined fresh tissue samples and obtained similar results as illustrated in Fig. 1.

The overall purpose of this work was to explore the applicability of the perchloric acid extraction technique for quantitative investigations of metabolites in placental tissue and to establish its correlation with gross placental tissue. As can be seen in Fig. 2, the spectrum from an extract gives significant peak enhancement and resolution and indeed allows observation of very small quantities of metabolic substrates such as phosphocreatine that are not easily observed in gross tissue. These extract spectra show that those from placentas are different from those seen in the heart,[16] which has relatively high concentrations of adenosine triphosphate and phosphocreatine, but are similar to those seen in liver, which has low concentrations of phosphocreatine.[17] This low phosphocreatine concentration found in placenta appears to be an intrinsic property

of this tissue, suggesting that other energy metabolism pathways aside from those driven by creatine kinase may also be significant.

In the performance of our spectral analysis, we noted that there were large amounts of inorganic phosphate in placental tissue. Quantitation with the same method described for quantitation of adenosine triphosphate yielded levels that ranged from 2.045 to 15.575 μmol per gram wet weight. Corrections were made for the inorganic phosphate resonances being only 97.4% relaxed under our spectral conditions. The levels calculated are significantly higher than the adenosine triphosphate levels (range, 0.404 to 0.709 μmol per gram). This is especially interesting because there are low levels of phosphocreatine and adenosine triphosphate. This large amount of inorganic phosphate most likely did not originate from phosphocreatine or adenosine triphosphate breakdown. It also does not appear that this is an indirect contribution from blood in the tissue inasmuch as our calculated concentration of inorganic phosphate is 0.647 μmol per milliliter of blood, or only 0.518 μmol per gram tissue. This suggests that inorganic phosphate in placenta may play a major role in other phosphorus metabolic processes aside from oxidative phosphorylation. Iles et al.[18] suggested that the inorganic phosphate seen in rat liver extracts may derive from labile organic phosphates that liberate inorganic phosphate on extraction or that the inorganic phosphate may exist in an available pool for metabolic processes. Inorganic phosphate in placenta probably

behaves in a similar fashion. Because glycolysis is an important process in the placenta, a large amount of inorganic phosphate may be needed to stimulate enzymes such as glyceraldehyde-3-phosphate dehydrogenase and 3-phosphoglycerate kinase, which are important enzymes in glycolysis. Perhaps future studies of inorganic phosphate levels in normal and abnormal placentas will prove to give informative biomedical insights.

The prominent peaks in the phosphomonoester and phosphodiester regions of the spectra should also be pointed out and may signify enhanced membrane synthesis that has previously been noted in spectra of tumors.[19] In many ways the placenta has been likened to a large, rapidly growing tumor.

One other aim in this study was to perform quantitation of phosphorus metabolites in our tissue extracts with a reference standard. Use of either external or internal intensity standards in our extracts allows quantitation of adenosine triphosphate levels and thus meaningful comparative analysis between different placentas. We are interested in the development of these methods because such analysis may allow metabolic studies of normal and abnormal placentas, which can be used to evaluate abnormal conditions such as those associated with growth-retarded infants. The levels of adenosine triphosphate identified in normal and abnormal placentas may ultimately be applied to in vivo placental studies. Clearly the absence of quantitation has presented a problem in many previous comparative nuclear magnetic resonance studies. The adenosine triphosphate concentrations measured here for human placental tissue fall in the range of 0.40 to 0.70 μmol per gram wet weight on the basis of a hexachlorocyclotriphosphazene standard. Whereas this is low compared with some other types of tissues, it agrees with published values from other placental studies that were in the range of 0.30 to 0.70 μmol per gram wet weight[20] as determined by spectrophotometric analysis and high-performance liquid chromatography on freeze-clamped tissue.

The external coaxial capillary method with hexachlorocyclotriphosphazene has the advantage that it is portable and can be used reproducibly both in extracts and in perfused tissue samples. Use of an external standard rather than an internal standard would minimize variability in extraction rates, a difficulty that can be encountered in perchloric acid extractions. Reproducibility of the current extraction and quantitation technique was tested with repetitive measurements on several tissue samples from the same placenta with essentially identical results.

The contribution of blood to the total adenosine triphosphate measured is an important consideration in studies of highly vascular organs such as kidney, liver, and vascular tumors that may not be commonly appreciated. Our calculations indicate that the blood component may account for as much as 30% to 50% of the total adenosine triphosphate in our samples. Therefore, it appears important to make corrections for the adenosine triphosphate component from blood when measuring the total adenosine triphosphate levels in vascular tissues. This by necessity will depend on the approximate blood volume present and an estimate of blood adenosine triphosphate levels for a representative blood sample. A correction of this type will be important not only in perchloric acid extracts but also in in vivo spectroscopy studies.

Argon laser versus microscissors for hysteroscopic incision of uterine septa

Giovanni Battista Candiani, MD, Paolo Vercellini, MD, Luigi Fedele, MD, Salvatore Garsia, MD, Diana Brioschi, MD, and Laura Villa, MD

Milan, Italy

We performed hysteroscopic metroplasty in 21 women with repeated abortion and subseptate uterus. The patients were randomly allocated to septal incision with the argon laser (group I, 10 subjects) or microscissors (group II, 11 subjects) to compare these instruments in terms of surgical feasibility and anatomic results. The mean operating time was 57% longer in group I than in group II (p = 0.001), the intra- and postoperative morbidity of the whole series was negligible, and the anatomic results at abdominal ultrasonography and hysteroscopy performed 2 months postoperatively were similar in the two groups. This study confirms that microscissors are the simplest, fastest, most effective, and least expensive instrument to correct a septate uterus. The complete agreement of the findings at follow-up hysteroscopy and ultrasonography suggest the use of the latter as the method of choice to check the surgical results. (Am J Obstet Gynecol 1991;164:87-90.)

Key words: Uterine malformations, recurrent abortion, hysteroscopy, laser

Hysteroscopic incision seems to be the method of choice to correct a septate uterus.[1-3] The endoscopic use of microscissors and the resectoscope has proved successful,[1-4] and hysteroscopic metroplasty with fiberoptic laser has been proposed.[5] We designed a randomized study to compare the surgical and anatomic results of section of the uterine septum performed with the argon laser versus microscissors.

Material and methods

During 1989 we studied 21 women with a mean age of 28 years (range, 23 to 34) with two or more spontaneous abortions, a double uterine cavity at hysterosalpingography (Fig. 1) and evidence of a normal uterine fundus at ultrasonographic examination with a half-full bladder.[6, 7] All the uteri were classified as American Fertility Society class Vb (partial septate uterus).[8]

After giving informed consent, the patients were allocated according to a randomization list to hysteroscopic metroplasty with argon laser (group I, 10 women) or microscissors (group II, 11 women) between day 7 and day 10 of the cycle. Preoperative hysterosalpingography and ultrasonography showed the septum was broad (>3 cm wide at the base) in two subjects in group I and in four subjects in group II. Under general endotracheal anesthesia and laparoscopic control, the cervix was dilated to 7 mm and a rigid hysteroscope (model 26157 B, Storz Endoscopy, Tuttlingen, Federal Republic of Germany) with a 7 mm diameter operating sheath (Storz model 26163 C and 26163 H) was introduced. The uterine cavity was distended with a 10% solution of dextran of molecular weight 40,000 in normal saline solution (Rheomacrodex, Baxter-Travenol, Trieste, Italy). In the group I women the septal incision was performed with the argon laser (model 20, HGM Medical Laser Systems Inc., Salt Lake City, Utah), passing the 0.6 mm flexible quartz fiber through the operating channel of the hystero-

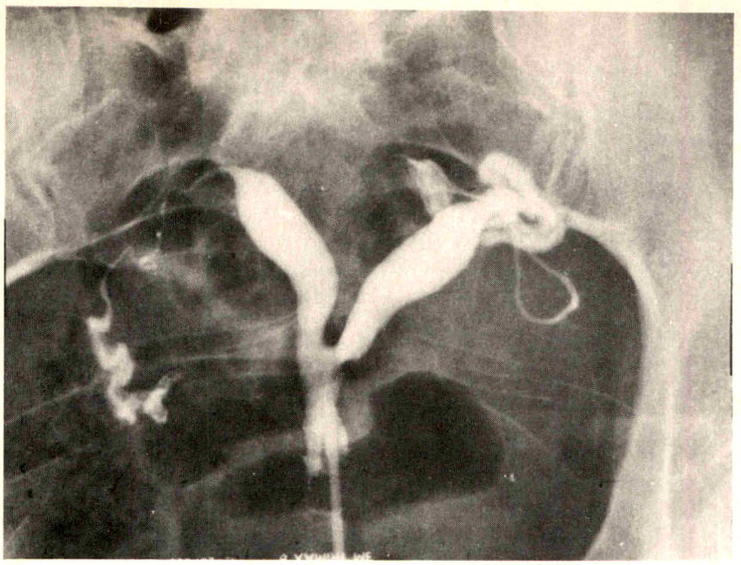

Fig. 1. Hysterosalpingogram of septate uterus before hysteroscopic metroplasty with argon laser.

scopic sheath and using a touch technique. The power was set at 12 watts in continuous mode. Rigid scissors (Storz model 26158 EK) were used in the group II patients.

After visualization of the tubal ostia, the section was started from the inferior margin of the septum and carried cephalad with progressive horizontal incisions in the midline. The six broad septa were sectioned with the technique suggested by March and Israel.[2] The incision was considered complete when a normal uterine cavity was obtained and the hysteroscope could be moved freely from one tubal ostium to the other. The operating time was calculated from the insertion of the flexible fiber or microscissors into the uterine cavity to the removal of the hysteroscope. No intrauterine contraceptive device was inserted and no pre- or postoperative hormone treatment was administered. The patients were scheduled to undergo transabdominal ultrasonography in the late secretory phase of the second postoperative cycle and follow-up hysteroscopy in the next proliferative phase. The ultrasonographist did not know the surgical results and the hysteroscopist was unaware of the ultrasonographic findings. For statistical analysis the Student *t* test and Fischer's test were used.

Results

All the procedures were completed without complications. Incision of the septum with argon laser was relatively slow and difficult. The mean operating time was 57% longer than with microscissors, the difference being 11 minutes (95% confidence limits, 5 to 17; Table I). This was attributable partly to the lower cutting capability of the laser fiber and partly to the difficult operating conditions and to the reduction of the visual field by the eye protection filter. The mean amount of distension medium used was 75% greater with the argon laser, with a difference of 333 ml (95% confidence limits, 105 to 561). The postoperative course was uneventful in all patients, and they were discharged within 24 hours.

At follow-up ultrasonographic examination a residual fundal notch ≥1 cm deep with respect to the orthogonal plane passing through the two tubal ostia was observed in two women in each group. Minor fundal irregularities (<1 cm deep) were present in four group I and five group II patients. The hysteroscopic findings always confirmed the ultrasonographic data. All the uterine cavities had a uniform lining of grossly normal endometrium. During the repeat hysteroscopy the four central fundal adhesions of ≥1 cm deep were sectioned. Three group I and two group II subjects had a follow-up hysterosalpingography that confirmed the ultrasonographic and hysteroscopic findings (Fig. 2).

Six patients who underwent surgery with the argon laser attempted to conceive: one aborted at 10 weeks' gestation, one took a pregnancy to term and was delivered vaginally, three are currently pregnant (14, 19, and 28 weeks, respectively), and one has not conceived after 6 months. Of the eight women who underwent surgery with microscissors who sought a pregnancy, one underwent right salpingectomy for ectopic pregnancy, one had a vaginal delivery at term, one had a cesarean section at 39 weeks' gestation for obstetric reasons, four have an ongoing pregnancy (7, 9, 18, and 26 weeks), and one has not conceived after 4 months.

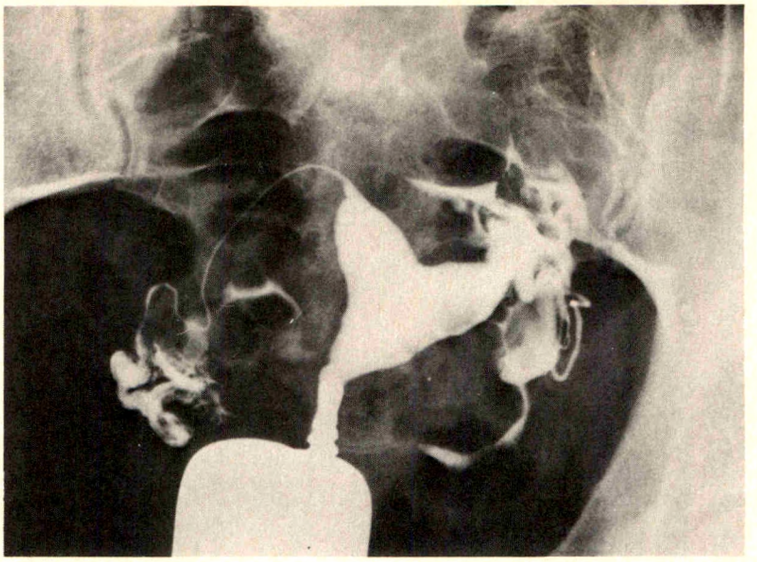

Fig. 2. Same case as in Fig. 1. Postoperative hysterosalpingogram shows minimal septal remnant <1 cm deep.

Comment

The argon laser is a simple instrument to use, and is practical and effective in the laparoscopic treatment of endometriosis.[9] Energy is delivered through a flexible quartz optical fiber of 0.3 or 0.6 mm diameter. Unlike the carbon dioxide laser, the argon laser can be used through clear fluids, and is thus suitable for operative hysteroscopy. Also the Nd-YAG laser can be used with fibers through fluids, but because of the power of its beam, which can penetrate to depths of 4 to 5 mm and thus effectively ablate endometrium,[10] it does not seem to be indicated in conservative intrauterine surgery where endometrial sparing is most important. The argon laser can coagulate small vessels and, when used at relatively high power settings with a near-contact or touch technique, the predominant effect is vaporization and incision with an extremely narrow band of thermal damage to surrounding tissues.[9] Because of these characteristics we considered the argon laser (the KTP/532 laser is not yet available in Italy) the best choice for a comparative study on microscissors, the current "gold standard" for hysteroscopic metroplasty.[1-3]

Our study had a major limitation, the small sample size, but it was designed as a pilot study to identify clinically important differences in the feasibility and duration of operation and in the postoperative anatomic results. This initial experience of hysteroscopic correction of septate uteri with the argon laser was unsatisfactory. The operating times were appreciably longer than when microscissors were used. The slowness of the incision could possibly be related to the range of light wavelength of the argon laser (488 to 514 mm), which is preferentially absorbed by tissues rich in red pigment such as hemoglobin, whereas the cut septum is white and avascular. When the section reaches the cranial part of the septum, arteriolar bleeding is frequently observed. The argon laser's power of coagulation seems of no advantage in these circumstances. In fact, as noted by others, bleeding from the incised septum is minimal: fundal bleeding is the physiologic sign that parietal myometrium has been reached.[1-3]

Table I. Data on hysteroscopic incision of uterine septa with argon laser or microscissors

	Group I, argon laser (n = 10)	*Group II, microscissors (n = 11)*
Operating time (min)	30 ± 7*	19 ± 6†
Range	16-41	12-37
Distension medium used (ml)	776 ± 228*	442 ± 266 ml‡
Range	340-1280	240-1150
No. of patients (%) with residual fundal notch ≥ 1 cm deep at follow-up ultrasonography and hysteroscopy	2 (20%)	2 (18%)

*Mean ± SD.
†$p = 0.001$ versus group I (Student's t test).
‡$p = 0.006$ versus group I (Student's t test).

After the section we did not insert an intrauterine contraceptive device nor did we administer estrogens inasmuch as in a previous study we had found these measures of no benefit.[11] Postoperative morbidity was negligible in both groups. We observed no differences in the intracavitary morphologic results after metroplasty with the argon laser compared with microscissors. The follow-up of the patients is too short to draw conclusions on the reproductive outcome.

As a secondary observation we found that the data obtained at the follow-up ultrasonographic examination corresponded to those of the "second look" hysteroscopy. If this finding is confirmed, it would mean that an ultrasonographic scan with half-full bladder[6, 7] would be sufficient to check the results of surgery before allowing patients to try to conceive. Hysteroscopy could be reserved for patients who require correction of deep septal remnants.

This study confirmed that microscissors are the most simple, rapid, effective, and economic instrument for hysteroscopic correction of a septate uterus. Other disadvantages of the argon laser include the necessity for running water to cool the laser generator and for a special three-phase electricity supply. The eye safety filter necessary to protect the operator's retina from backscatter alters color perception, reduces the field of view, adds an extra encumbrance to the eyepiece of the hysteroscope, and makes photographic or television documentation of the operation difficult. It takes longer to learn to use the argon laser than microscissors in hysteroscopy. Lastly, an argon laser has a very high initial cost and should be acquired only by hospitals that can amortize the expense on a large number of endoscopic operations. Otherwise the economic advantage of hysteroscopic metroplasty[3] is lost.

Angiosarcoma of the uterus: A case report

Guillermo E. Quinonez, MD, MSc, Maria P. Paraskevas, MD, MSc, Malkit S. Diocee, EMT, and Susan M. Lorimer, MD

Winnipeg, Manitoba, Canada

We are reporting a case of angiosarcoma of the uterus in which the diagnosis was confirmed ultrastructurally by demonstration of Weibel-Palade bodies in the tumor cells. Only 10 cases of this entity have been previously documented in the literature. (Am J Obstet Gynecol 1991;164:90-2.)

Key words: Uterine angiosarcoma, Weibel-Palade bodies

From the Department of Pathology, Health Sciences Centre, Faculty of Medicine, University of Manitoba.

6/1/24446

Angiosarcomas of the uterus are rare. Ten cases have been previously documented in the literature.[1, 2] We are reporting a case of angiosarcoma of the uterus in which the diagnosis was confirmed ultrastructurally by demonstrating Weibel-Palade bodies.

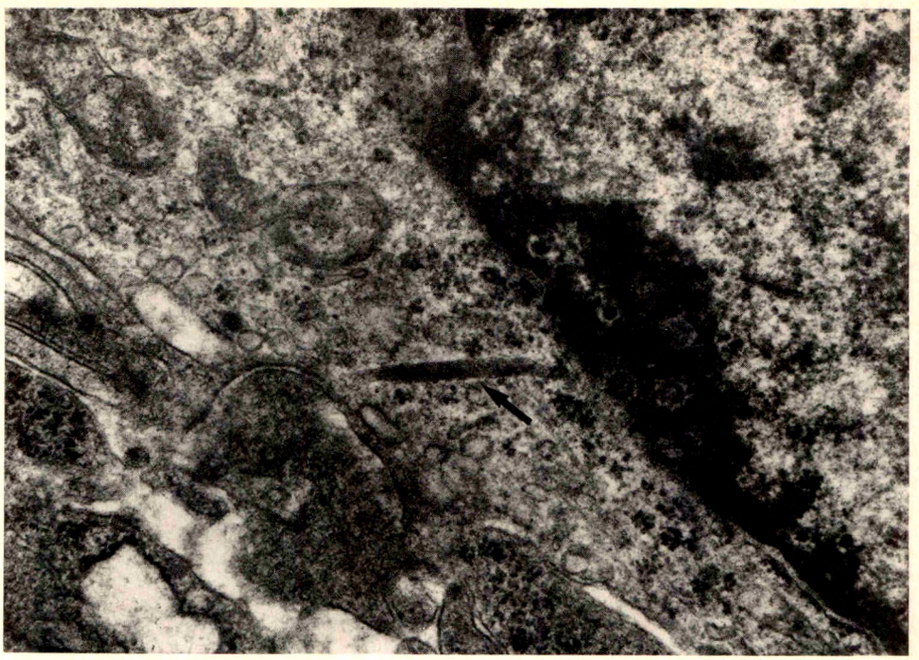

Fig. 1. Weibel-Palade body is seen at center of figure *(arrow)*. Micropinocytotic vesicles and long cytoplasmic extensions from neighboring cells are also seen. Intermediate junctions are present between those extensions (center, upper part). (×36,000.)

Case report

A 65-year-old woman presented to her family physician in April 1985 with postmenopausal bleeding. A curettage was performed, and findings were interpreted as angiosarcoma. Results of endocervical curettage were noncontributory.

Gynecologic history included menarche at age 14 and normal regular menses. She was gravida 3, para 3 and had uneventful vaginal deliveries. She had had two previous curettages because of perimenopausal bleeding in 1967 and postmenopausal bleeding in 1982. Results of both curettages were reported as unremarkable.

Two months before this hospital admission, she noted increasing fatigue and a 10-pound weight loss over the last 2 weeks. A general physical examination showed her condition to be essentially normal. Pelvic examination showed a brownish red discharge from the endocervix. The uterus was bulky and measured approximately 7.5 cm in length. Adnexal and rectal examinations gave negative results. Findings on intravenous pyelography and barium enema were negative. The hemoglobin level was 116 mg/L, white blood cell count was 8000/ml, and platelet count was 298,000/ml. The patient underwent total abdominal hysterectomy, bilateral salpingo-oophorectomy, and selective pelvic lymphadenectomy followed by vaginal insertion of cesium and nine courses of combination chemotherapy with cisplatin and Adriamycin. At the last follow-up visit in March 1989, the patient was clinically free of disease. A vaginal smear showed no abnormal cells and the chest x-ray film did not show any abnormalities.

Tissue received at the laboratory consisted of uterus with adnexa, right and left pelvic nodes, and omental biopsy specimen. The uterus weighed 100 gm. The endometrial cavity measured 3.5 × 2.4 cm. Arising from the anterior aspect of the uterus, toward the fundus, was a large hemorrhagic mass measuring 4.7 × 4 cm and raised 1.9 cm above the endometrial layer. On section, this mass had a gray hemorrhagic appearance and a finely lobulated pattern. An additional satellite nodule measuring 0.9 cm in diameter was present posteriorly at the fundus, toward the right cornu. Tubes and ovaries were atrophic and otherwise unremarkable.

Microscopic sections of the hysterectomy specimen showed an endometrial tumor similar to the reviewed curettage specimen. It consisted mostly of solid masses of pleomorphic and spindle cells forming communicating channels filled with blood. The nuclei were irregular and hyperchromatic with occasional nucleoli, and the cytoplasm was eosinophilic with no obvious cytoplasmic borders; mitoses were up to 6 per 10 high-power fields. True blood vessels were not found within the tumor. Reticulin stain showed abundant reticulum network outlining interconnecting spaces. The tumor infiltrated the myometrium irregularly and extended to half its thickness. The satellite nodule showed similar histologic features. The remaining endometrium showed only cystic and atrophic glands. Pelvic nodes and omentum were free of tumor.

Ultrastructurally, cells lining the vascular spaces showed micropinocytotic vesicles and, not infrequently, Weibel-Palade bodies (Fig. 1). Factor VIII–related antigen immunocytochemical stain was negative in the tumor cells.

Comment

The present case was that of a 65-year-old woman presenting with postmenopausal bleeding who underwent surgical treatment and chemotherapy after diagnosis of angiosarcoma of the uterus. She was doing well 4 years after operation. This clinical history is similar to some of the cases previously reported.[1, 2]

This case showed, by light microscopy, typical features of a vascular tumor, the pattern of which was well demonstrated by reticulin stain. The true vascular nature of the tumor was confirmed by demonstrating Weibel-Palade bodies in the tumor cells ultrastructurally. An immunocytochemical test for Factor VIII–related antigen gave negative results. A negative result of Factor VIII–related antigen staining does not rule out the diagnosis of angiosarcoma since Factor VIII–related antigen positivity is highly variable in cases of angiosarcoma (65% to 95%).

This report adds a new case of this extremely rare entity. It confirms ultrastructurally, for the first time in a published case, the vascular nature of the neoplasm by demonstrating Weibel-Palade bodies in the tumor cells.

We thank Dr. A. Alguacil-Garcia for his comments.

Quantitative and qualitative platelet abnormalities during pregnancy

Helen Y. How, MD, Frauke Bergmann, MD, Mabel Koshy, MD, Juan Chediak, MD, Celeste Presperin, RN, and Stanley A. Gall, MD

Chicago, Illinois

In a 1-year period, 15 of 4048 pregnant women were found to have thrombocytopenia during their first prenatal visit. Their qualitative and quantitative platelet abnormalities were followed up prospectively for 1 to 6 months post partum. Platelet counts returned to normal in 14 of 15 patients 4 to 6 weeks post partum. von Willebrand factor antigen and ristocetin cofactor activity were low in three of 15 patients 4 to 6 weeks post partum, but had been normal during the antepartum period. Two of these three patients had prolonged bleeding times ante partum and post partum. All three patients subsequently were found to have mild type I von Willebrand disease. Six patients had detectable platelet antibodies. Neonatal thrombocytopenia was found in one term infant of a patient with mild thrombocytopenia and negative platelet antibodies. This study suggests that mild, transient, isolated thrombocytopenia can occur in an otherwise normal pregnancy and its incidence may be lower than previously reported. Extensive testing is not indicated unless there is an associated prolonged bleeding time. The possibility of von Willebrand disease or a qualitative platelet disorder should be considered. (Am J Obstet Gynecol 1991;164:92-8.)

Mild, transient, isolated thrombocytopenia has been reported to occur during pregnancy with a frequency of 7.6% to 24%.[1, 2] Postulated causes of this transient mild thrombocytopenia include immune complex deposition on platelets during a viral infection with removal from circulation,[1] chronic intravascular coagulation during normal pregnancy,[3] and the "tail end" of a normal platelet distribution.[4] All re-

ported cases had uncomplicated perinatal and maternal outcomes[1-3]; however, none of the reports has evaluated the patients for the presence of qualitative platelet defects associated with the thrombocytopenia. The purpose of our prospective study was as follows: (1) determine the incidence of thrombocytopenia at the time of the first prenatal visit; (2) assess whether mild thrombocytopenia was associated with a qualitative platelet abnormality; (3) determine whether there was a correlation between thrombocytopenia and abnormal levels of von Willebrand factor; and (4) develop guidelines for appropriate management of this condition.

Material and methods

All pregnant women attending the obstetric outpatient clinic at the University of Illinois Hospital at Chicago from August 1987 to August 1988 were screened for thrombocytopenia at the time of their first prenatal visit. Thrombocytopenia during pregnancy is defined as a platelet count of $\leq 150{,}000/\mu l$.[5] Patients with thrombocytopenia associated with diagnosed collagen vascular disease, preeclampsia-eclampsia, drug ingestion, infection, hemoglobinopathies, immune thrombocytopenic purpura, and other systemic diseases were excluded. Only patients with newly identified thrombocytopenia without a known cause were included in the study.

After written informed consent was obtained, the study patients were followed up throughout the prenatal and postpartum periods. A detailed medical and obstetric history including evidence of a bleeding diathesis and nutritional status and a complete physical examination were obtained for all patients. Laboratory evaluation included a complete blood count with platelet count and mean platelet volume, bleeding time, antinuclear antibody, rheumatoid factor, prothrombin time, activated partial thromboplastin time, fibrinogen, fibrin split products, serum folate, vitamin B_{12}, platelet antibody, serum albumin levels, von Willebrand factor antigen (vWF:Ag) and ristocetin cofactor activity (vWF:RiCof) assays. The complete blood count with platelet count was repeated every 2 to 4 weeks as indicated until 4 to 6 weeks post partum. Bleeding time, vWF:Ag, vWF:RiCof, and platelet antibody measurements were repeated at 4 to 6 weeks post partum and again at 5 to 6 months post partum if necessary.

Complete blood count, platelet count, and mean platelet volume measurements were performed on venous blood anticoagulated with ethylenediaminetetraacetic acid (EDTA) with an automated counter (S-Plus IV model, Coulter Electronics, Hialeah, Fla.). The coefficient of variation for platelet count is 2.3%. The degree of thrombocytopenia was confirmed by examination of the stained peripheral blood smear to exclude the presence of platelet clumping and other hematologic disorders.

Modified Ivy bleeding time measurements were performed with a Simplate single blade automatic device (General Diagnostic, Morris Plaines, N.J.). The normal bleeding time ranges between 2 and 8 minutes.

Blood specimens for coagulation studies were collected in Vacutainers blood collecting tubes containing 3.8% sodium citrate in a ratio of 9:1 (blood/citrate). Platelet-poor plasma was obtained by centrifugation of the blood samples at 3300 *g* at 2° C. An aliquot of the plasma was stored in plastic tubes at −70° C until tested. Pooled plasma specimens from at least 20 normal control subjects (males and females) was used as a reference plasma for all procedures. Each test was performed twice and the average was reported. The quantification of vWF:Ag was performed with the Laurell immunoelectrophoresis[6] with an antibody (Behring Diagnostic, La Jolla, Calif.) to von Willebrand factor. The functional activity of von Willebrand factor was measured by use of a nephelometer (Chronolog Corp., Havertown, Pa.) in accordance with the procedure by Weiss[7] with the following modifications. Washed platelets (with artificial media) of a healthy control subject at a concentration of $380{,}000/\mu l$ were used. A 100% standard was obtained by use of pooled normal plasma; 0.12 ml of plasma and 0.4 ml of the platelet suspension were mixed in a cuvette with 0.02 ml of calcium chloride (1.5 mg/ml) at 37° C. Agglutination was induced by addition of 0.04 ml of ristocetin (22 mg/ml 0.9% normal saline solution). Because ristocetin is used as a ligand and this method checks the activity of von Willebrand factor, this test is known as the vWF:RiCof assay. To differentiate the various subtypes of von Willebrand disease, the multimeric distribution of von Willebrand factor was determined with a 1.4% low-temperature agarose gel (Type VII, Sigma Chemical Co., St. Louis) following a modified method of Ruggeri and Zimmerman.[8]

Unbound platelet antibodies were measured with the fluorescence activated flow cytometry method and results were reported as a reciprocal of a titer (Meth Path, Teterboro, N.J.).[9] Fibrinogen was determined with reagents purchased from Dade Diagnostic Inc. (Miami). Fibrin split products were measured with monoclonal antibody–coated latex particles (American Diagnostica Inc., New York). Prothrombin time and activated partial thromboplastin time were determined following the coag-A-mate operator's manual provided by General Diagnostic. Albumin was measured spectrophotometrically at 630 nm after binding to bromocresol green dye. Urine toxicology screen was performed by fluorescence polarization immunoassay with a therapeutic drug analyzer (Abbot, Irving, Tex.). The following drugs and their metabolites were checked: barbiturates, benzodiazepines, cocaine, opiates, phencyclidine, amphetamine, methamphetamine, and cannabinoids. Rheumatoid factor was determined by use of Behring's

B, Black; *H*, Hispanic; *ANA*, antinuclear antibody; *FTA*, fluorescent treponemal antibody-absorbed test; *RPR*, rapid plasma reagin test.

Rapi Tex RF test (Sommerville, N.J.). Antinuclear antibody test was determined by staining the antigen-antibody complex formed in the presence of antinuclear antibody with fluorescein-labeled antihuman globulin (Antibodies Inc., Davis, Calif.).

Comparisons of platelet counts measured on the same persons during the course of their pregnancies were analyzed with a randomized, block design analysis of variance. Comparison of vWF:Ag and vWF:RiCof between normal pregnancies and pregnancies with subsequent diagnosis of von Willebrand disease were performed with the Student *t* test for independent samples.

Results

In our patient population, 15 of 4048 patients met the diagnostic criteria for transient thrombocytopenia. Eight other patients were excluded from the study: three with thrombocytopenia associated with collagen vascular disease; two with preeclampsia-eclampsia; one for drug ingestion; and two with immune thrombocytopenic purpura.

The mean maternal age was 24 years (range, 15 to 38). Five patients were primigravid and 10 were multiparous. Eight were black and seven were Hispanic (Table I). All patients denied the ingestion of medications known to affect platelet function.

Ten of the 15 patients had persistent antepartum thrombocytopenia in at least three consecutive determinations (mean platelet count ± SEM of 112,638 ± 2,877/μl). Of the remaining five patients who had their initial evaluation in the third trimester, three patients (Nos. 2, 6, and 12) had only one of their three serial platelet counts in the thrombocytopenic range (98,000, 121,000, and 125,000/μl, respectively); the other two had counts in the thrombocytopenic range in more than one sample. The mean platelet count ± SEM at initial diagnosis for the 15 patients during the antepartum period was 118,620 ± 5040/μl and was significantly lower than the mean of 193,460 ± 10,890/μl seen in the same patients at 4 to 6 weeks post partum ($p << 0.0001$). The platelet counts of 14 (93.3%) patients were normal at 4 to 6 weeks post partum. Only patient No. 5 remained slightly thrombocytopenic (146,000/μl), and mild type I von Willebrand disease was subsequently diagnosed. The mean platelet count for the 15 patients was 137,460 ± 18,190/μl at delivery and 133,150 ± 14,480/μl 1 to 5 days post partum (Fig. 1). These values were not significantly different from the antepartum values but were significantly different from the 4- to 6-week postpartum value ($p << 0.002$ and $<< 0.001$, respectively). The mean platelet volume did not change significantly throughout the prenatal, peripartum, and postpartum course.

Five of the 15 patients (33.3%) had a prolonged bleeding time (Table II). Type I von Willebrand disease was diagnosed on the basis of additional laboratory data in two of the patients (Nos. 5 and 7) who had persistently prolonged bleeding time (>15 minutes) during the postpartum period. The bleeding time in the remaining three patients returned to normal values in the postpartum period.

Six of the 15 patients (Nos. 2, 3, 5, 7, 8, and 13) had positive unbound platelet antibodies. One of these six

patients (No. 3) had unbound platelet antibodies ante partum and post partum. Her titer was 1:16 at 25 weeks' gestation; it increased to 1:128 at 1 to 5 days post partum and decreased to 1:64 at 4 to 6 weeks post partum. Two other patients (Nos. 2 and 8) had unbound platelet antibodies detected only ante partum; their titers were 1:2 at 34 weeks' gestation and 1:8 at 37 weeks' gestation, respectively. Thrombocytopenia was not found in the infants born to these three mothers. The remaining three patients (Nos. 5, 7, and 13) had unbound platelet antibody detected during the postpartum period. Patient No. 5 had a titer of 1:64

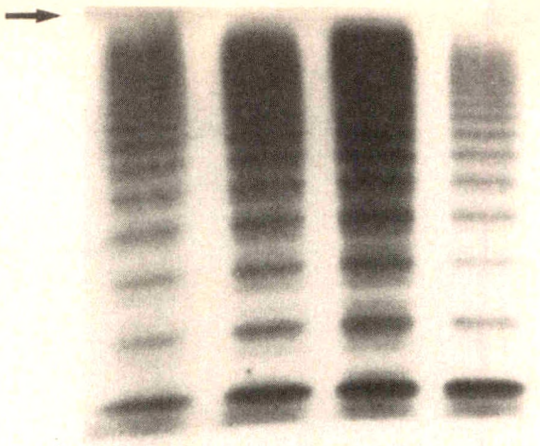

Fig. 2. Autoradiogram of sodium dodecylsulfate-agarose gel electrophoresis of plasma von Willebrand factor of patient No. 6. For comparison, multimeric distribution of pooled normal plasma *(PNP)* is shown on left. *Arrow* indicates top of running gel. Tests were run at different time intervals during antepartum and postpartum periods. Actual values of vWF:Ag and vWF:RiCof are shown at bottom.

†n = 3.

at 4 to 6 weeks post partum; it decreased to 1:16 at 3 to 4 months post partum. Patient No. 7 had a titer of 1:8 at 4 to 6 weeks post partum and 1:4 at 5 months post partum. Patient No. 13 had a low titer of 1:4 at 4 to 6 weeks post partum (Table II).

The antepartum values of vWF:Ag and vWF:RiCof in three patients (Nos. 5, 6, and 7) subsequently diagnosed with mild von Willebrand disease were lower but not significantly different from those of pregnant patients without this disorder. However, the postpartum values were significantly lower ($p < 0.005$). The diagnosis of von Willebrand disease was made 4 to 6 weeks post partum and was confirmed 5 to 6 months post partum (Table III). The analysis of von Willebrand factor multimers and associated laboratory data of patient No. 6 are shown in Fig. 2. There was no clinical reason to examine the patients without von Willebrand disease 5 to 6 months post partum.

One of 15 (6.6%) term infants was born with neonatal thrombocytopenia (78,000/μl; normal range, 100,000 to 280,000/μl).[10] The mother (patient No. 15) had thrombocytopenia (97,000/μl) and a prolonged bleeding time (10 minutes) with no other clinical abnormalities noted. The mean platelet count of the remaining 14 infants was 263,250 ± 27,796/μl.

The serum folate level, vitamin B_{12} level, prothrombin time, activated partial thromboplastin time, fibrinogen, fibrin split products, albumin level, and rheumatoid factor slide test results of all the patients studied were within normal limits. Similarly, urine toxicology screen was negative in all except patient No. 12 whose test was positive for cocaine and marijuana. Antinuclear antibody was positive for patients Nos. 1 and 8 (Table I).

Twelve of the 15 patients had a spontaneous vaginal delivery and three patients were delivered of infants by cesarean section. Patient No. 7 had decreasing serial platelet counts during the prenatal course. Her platelet counts were 118,000/μl at 25 weeks' gestation and 95,000/μl at 37 weeks. Cordocentesis was recommended to rule out the possibility of an immune-mediated thrombocytopenia. However, a low transverse cesarean section had to be performed when fetal bradycardia in association with hemorrhage at the umbilical cord's puncture site was noted. Consequently, no cordocentesis was recommended for subsequent patients unless immune thrombocytopenic purpura was definitely suspected. Patient No. 9 had a low transverse cervical cesarean section because of failure to progress. Patient No. 5 received 10 units of platelet concentrates 30 minutes before a repeat cesarean section to correct a prolonged bleeding time. None of these 15 patients, including those with a subsequent diagnosis of von Willebrand disease, had peripartum hemostatic complications.

Comment

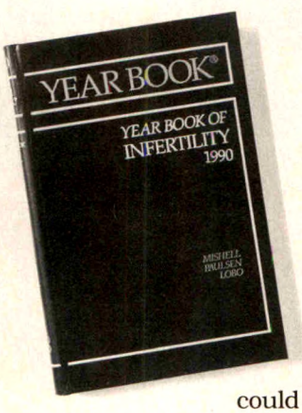
Platelet counts in pregnant women remain within the established range even in the presence of hemodilution, placental trapping, or platelet hyperdestruction.[5, 11] However, recent publications have reported low platelet counts during uncomplicated pregnancy with no overt consequence to the mother and fetus.[1, 2, 4] The cause of the mild transient thrombocytopenia is still unknown.

Von Willebrand factor plays a role in platelet adherence to subendothelium and aggregation in response to ristocetin and has been implicated in the pathogenesis of thrombocytopenia in patients with clinical disorders such as thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and preeclampsia-eclampsia. A similar mechanism could explain the mild thrombocytopenia observed during some pregnancies. von Willebrand factor is synthesized in endothelial cells and found in megakaryocytes. It is stored in Weibel-Palade bodies of endothelial cells and α-granules of platelets. Under certain physiologic conditions, such as stress or pregnancy, von Willebrand factor is released into circulation or deposited in the subendothelium as multimers of variable molecular weight. The biologic activities of von Willebrand factor include platelet-to-platelet interaction and platelet adhesion to the vessel wall. It also functions as a carrier protein for Factor VIII coagulant in plasma. Quantitative and qualitative abnormalities of von Willebrand factor cause a bleeding disorder known as von Willebrand disease. Its main symptoms are easy bruising, severe menstrual bleeding, and prolonged bleeding after injury or surgery. The diagnosis usually is established by a family history of a bleeding diathesis, a prolonged bleeding time, and low levels of vWF:Ag and vWF:RiCof. The classification of von Willebrand disease into subtypes is made on the basis of the multimeric characteristics of von Willebrand factor. In type I, the most common form, vWF:Ag and vWF:RiCof are decreased in parallel and all multimers are present to a lesser degree. In type II, the high molecular weight forms are missing.[12]

No patient was thought to have von Willebrand disease on the basis of her history; however, because bleeding time and von Willebrand factor activity were part of the evaluation, these tests helped us diagnose the disorder in three patients. The thrombocytopenia improved in the postpartum period in patients both with and without von Willebrand disease. A follow-up of the mean platelet volume did not correlate with the shift in platelet counts, making hemodilution a more likely cause than an increase in platelet turnover. Because thrombocytopenia was diagnosed during pregnancy, we did not subject the patients to radiolabeled platelet studies to determine platelet survival. The bleeding time of the three patients with von Willebrand disease was persistently prolonged throughout the antepartum and postpartum period in two patients and normal in one patient. However, the latter was started on birth control pills 2 weeks post partum and hence may have had her expected prolonged bleeding time masked during the postpartum period. The platelet counts of two of the three patients with von Willebrand disease returned to normal during the postpartum period. Conti et al.[13] also reported mild thrombocytopenia in one patient with type I von Willebrand disease during pregnancy. When type I von Willebrand disease is present during pregnancy, desmopressin (1-Desamino-8-D-arginine-vasopressin, DDAVP) 0.4 μg/kg may be given 30 minutes before delivery to prevent or decrease potential hemostatic complications.[14]

To extend diagnostic possibilities, we measured unbound platelet antibodies. The level of maternal

unbound platelet antibodies in patients with immune thrombocytopenic purpura has been correlated with both the presence and the extent of neonatal thrombocytopenia[15]; however, the level's predictive value is confounded by the presence of measurable levels of maternal and umbilical cord unbound platelet antibodies because of nonspecific activity found in a normal pregnancy.[16] This was evident in our study; three mothers with unbound platelet anibodies detected during prenatal period were delivered of three infants with normal platelet counts. The detection of unbound platelet antibodies in one of the patients post partum may have resulted from preoperative platelet transfusions. The other two patients whose unbound platelet antibody was detected only post partum may have had an antigen-antibody reaction resulting from fetomaternal transfer of heterogeneous platelet antigen that might have occurred during pregnancy.



We found the incidence of thrombocytopenia to be 0.4% at the time of the first visit. This apparent low incidence compared with the other recent articles may be a result of the design of the study in which thrombocytopenia that developed in patients later in the course of pregnancy could be missed.

In conclusion, our study suggests that incidental, mild thrombocytopenia during pregnancy is often benign and transient. Extensive testing, such as those mentioned in our Material and methods section, is not indicated in such cases unless there is an associated prolonged bleeding time or persistent thrombocytopenia 4 to 6 weeks post partum. von Willebrand disease should then be considered. Three of the 15 patients had mild type I von Willebrand disease; however, because vWF:Ag and vWF:RiCof levels were elevated during pregnancy, the diagnosis could be made only in the postpartum period. Repeat platelet count at 6 to 8 weeks interval to observe its trend may be performed as clinically indicated. From the results of our study, neonatal thrombocytopenia seems unlikely to occur in the presence of mild transient maternal thrombocytopenia. In our series only one term infant showed mild thrombocytopenia. This indicates that vaginal delivery is safe and that abdominal delivery should be performed only in the presence of obstetric indications.

Okay. So we went a little overboard. But we could go on and on about the *Year Book of Infertility*. We could gush about how it gives you abstracts of the 310 most important articles from the past year. And we could carry on about our distinguished editors who comment on the significance and clinical application of the abstracts.

But let's be honest, you've probably seen other publishers use these same words to describe their products. And no list of adjectives can really convey a book's usefulness and value. *You've got to evaluate it for yourself.*

That's why we're offering you this no-risk, no-obligation, 30-day, free trial of the *Year Book of Infertility*. Just give us a call or drop this coupon in the mail and we'll send you a free examination copy. Put it to work for a month, and if you're not completely satisfied, just send it back and owe nothing.

We are confident, however, that you'll want to add a few adjectives of your own to this list—extraordinary, delectable, and revolutionary are still available.

❑ **Yes!**
Please send my free 30-day examination copy of the *1990 Year Book of Infertility* (20414). If I decide to keep the book I'll pay just $51.95 plus shipping and handling.

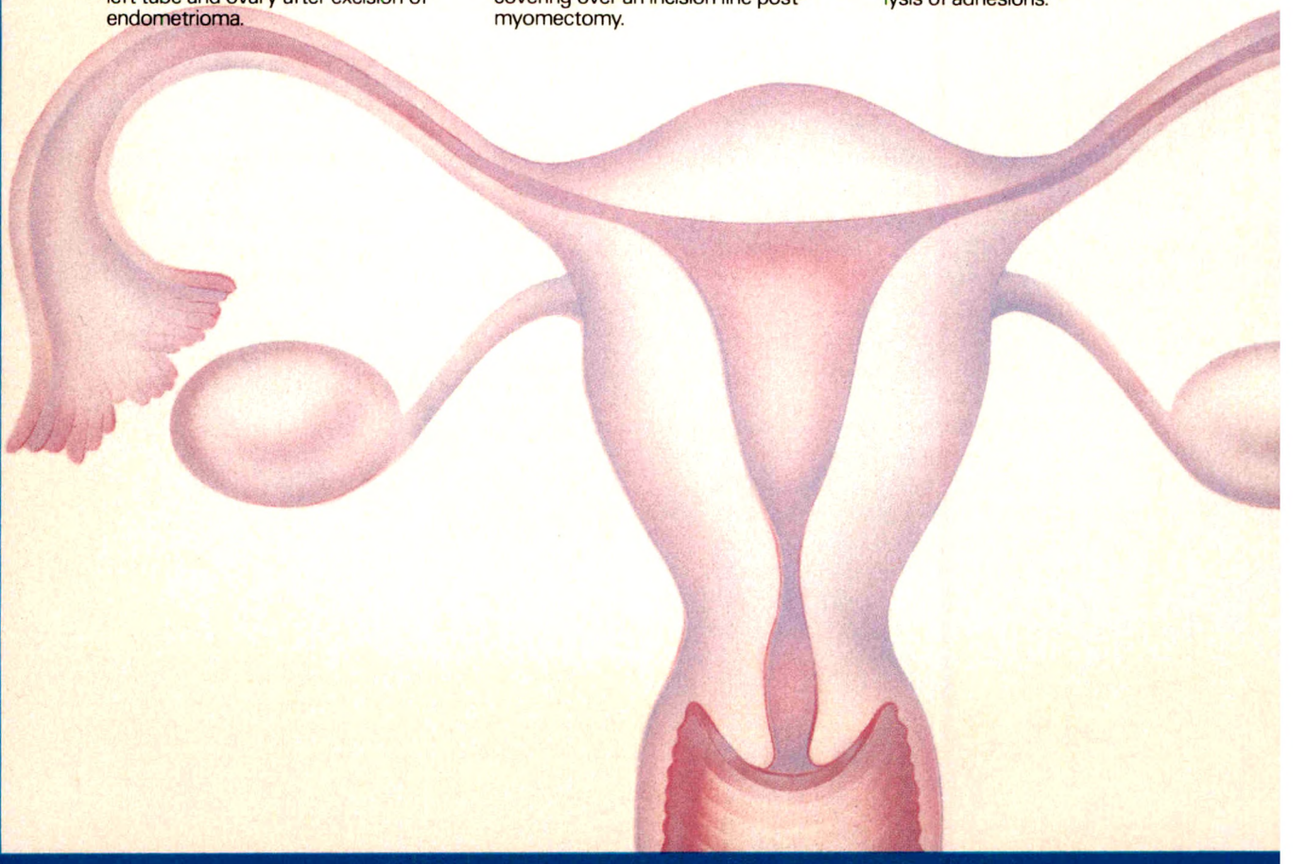
This Year Book is published annually. For the convenience of our customers, Mosby-Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements approximately 2 months before publication. The new volume will be shipped upon publication unless you complete and return the announcement requesting cancellation within the time indicated. You may cancel your subscription at any time. Each new volume may be examined for 30 days, and may be returned for full credit. Return postage is guaranteed.

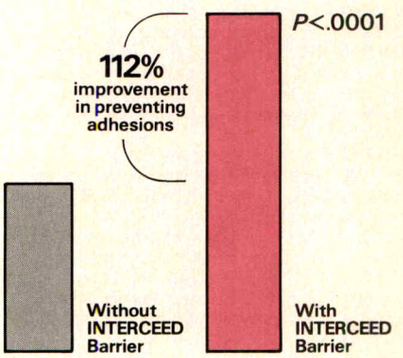
To significantly reduce adhesions...



The first proven adhesion barrie

INTERCEED Barrier conforms to left tube and ovary after excision of endometrioma.

INTERCEED Barrier provides a protective covering over an incision line post-myomectomy.



INTERCEED Barrier covering ovary post-lysis of adhesions.

for gynecologic pelvic surgery

Twice as effective as state-of-the-art surgery alone[1]

In a controlled, multicenter study of 134 patients known to have formed bilateral pelvic adhesions previously, INTERCEED®(TC7) Absorbable Adhesion Barrier was more than *twice* as effective (51% vs 24%) in preventing recurrence of adhesions when compared with state-of-the-art surgical techniques alone.

The first surgical adjuvant specifically indicated to reduce postoperative adhesions

- No complications–material completely absorbed within 28 days
- Minimal tissue reaction–significantly less than other absorbable products
- Sutures not required–adheres well to serosal tissue
- Compatible with both laparotomy and laparoscopic techniques[2]

Clinically Proven

INTERCEED®(TC7)

Absorbable Adhesion Barrier

(OXIDIZED REGENERATED CELLULOSE)

Johnson & Johnson

MEDICAL INC.

Please see following page for brief summary of Prescribing Information.

Clinically Proven
INTERCEED®(TC7)
Absorbable Adhesion Barrier
(OXIDIZED REGENERATED CELLULOSE)

Brief Summary for INTERCEED® (TC7) Absorbable Adhesion Barrier (Oxidized Regenerated Cellulose). Before prescribing, please see full prescribing information.

INDICATIONS: INTERCEED Barrier is indicated as an adjuvant in gynecologic pelvic surgery for reducing the incidence of postoperative pelvic adhesions after hemostasis is achieved consistent with microsurgical principles.
CONTRAINDICATIONS: The use of INTERCEED Barrier is contraindicated in the presence of frank infection.
INTERCEED Barrier is not indicated as a hemostatic agent. Appropriate means of achieving hemostasis must be employed.
WARNINGS: INTERCEED Barrier must not be used in cases in which complete hemostasis has not been established. The effectiveness of INTERCEED Barrier is reduced when saturated with blood.
INTERCEED Barrier is supplied sterile. As the material is not compatible with autoclaving or ethylene oxide sterilization, INTERCEED Barrier must not be resterilized.
Although none have been reported, foreign body reactions may occur in some patients.
PRECAUTIONS: The safety and effectiveness of using INTERCEED Barrier in combination with other adhesion prevention treatment have not been clinically established.
Ectopic pregnancies have been associated with fertility surgery of the female reproductive tract. No adequate and well controlled studies have been conducted in women who become pregnant within the first month after exposure to INTERCEED Barrier. No data exist to establish the effect, if any, of INTERCEED Barrier on the occurrence of ectopic pregnancies. No teratogenic studies have been performed. Therefore, an avoidance of conception should be considered during the first complete menstrual cycle after use of INTERCEED Barrier. Care should be exercised in applying INTERCEED Barrier to a pelvic organ not to constrict or restrict it.
ADVERSE REACTIONS: To date, no adverse reactions have been reported attributable to the use of INTERCEED Barrier.
CAUTION: Federal law restricts this device to sale, distribution, or use by or on the order of a physician.

Mosby Year Book

Provide vital information to those who need it most . . . with article reprints from Mosby–Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby–Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:

- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information

Article reprints . . . another valuable service from Mosby–Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby–Year Book periodicals are available from the Publisher.

The clinical implications of subchorionic placental lucencies

Vern L. Katz, MD, George F. Blanchard, Jr., BA, RDMS, William J. Watson, MD, Richard C. Miller, MD, Nancy C. Chescheir, MD, and John M. Thorp, Jr., MD

Chapel Hill, North Carolina

Forty-six patients were identified at a perinatal diagnostic referral center as having subchorionic placental lucencies. These lucencies varied from simple to multicystic and covered up to 50% of the subchorionic placental surface. Clinical follow-up of 40 patients demonstrated no increase in the incidence of adverse pregnancy outcome. We conclude that these pregnancies are not at higher risk when the subchorionic placental lucencies are not associated with other intraplacental or fetal anomalies. (Am J Obstet Gynecol 1991;164:99-100.)

Key words: Placenta, ultrasonography, subchorionic lucencies

Subchorionic placental lucencies are a common cause of referral for detailed ultrasonographic examination and/or perinatal consultation. Spirt et al.,[1] in 1978, evaluated 10 patients with subchorionic placental lucencies of various sizes and obtained histologic diagnoses. These lucencies corresponded to areas of subchorionic fibrin deposition, a normal finding in 10% to 15% of pregnancies.[2] This investigation sought to evaluate the clinical implications of large subchorionic placental lucencies detected on ultrasonography to assess the importance and need for consultation.

Methods

Over a 6-month period, 1856 patients were referred for detailed ultrasonographic evaluation. Patients with greater than 2 × 2 cm subchorionic placental lucencies were identified prospectively and clinical outcomes were obtained. Cases were managed as clinically appropriate for respective referral indications.

Results

In this group of 56 referral patients, 18 were identified as having subchorionic lucencies. Of these, 14 were referred for evaluation of fetal anatomy, 10 because of increased maternal age, 8 because of low maternal serum α-fetoprotein level, 6 for examination of placental anomalies, 4 because of elevated serum α-fetoprotein level, and 4 because of maternal diabetes. The mean gestational age at examination was 19.3 weeks (range 13 to 34 weeks).

Representative illustrations of the placental lucencies are shown in Fig. 1. Lucencies varied from simple to multicystic. None were immediately below the umbilical cord insertion, and only one was associated with an intraplacental lucency. The lucencies covered from 10% to 50% of the placental surface by estimation and were from 2 to 6 cm in longest dimension.

Follow-up was obtained on 40 of 46 pregnancies. There were two perinatal deaths, one in association with neonatal complications of immune hydrops in an Rh-sensitized patient and one in conjunction with a premature birth in a twin pregnancy. Neither death appeared to be related to placental abnormality. The second twin is alive and thriving. One patient had premature labor at 32 weeks with delivery at term. One patient had meconium-stained amniotic fluid. There were seven cesarean births (17%), similar to occurrence in the general obstetric population. No patient reported bleeding in the third trimester. One patient had pregnancy-induced hypertension at term. All 14 amniocenteses produced normal karyotypes and normal α-fetoprotein levels. There were two congenital anomalies observed in the 46 fetuses, a mild unilateral hydronephrosis found at ultrasonography and a dislocated hip found at birth.

Comment

Subchorionic placental lucencies do not appear to be associated with adverse pregnancy outcomes. The clinical course of this group of patients is similar to what would be expected in the general population. The incidence of elevated maternal serum α-fetoprotein in patients with lucencies was similar to that of our referral

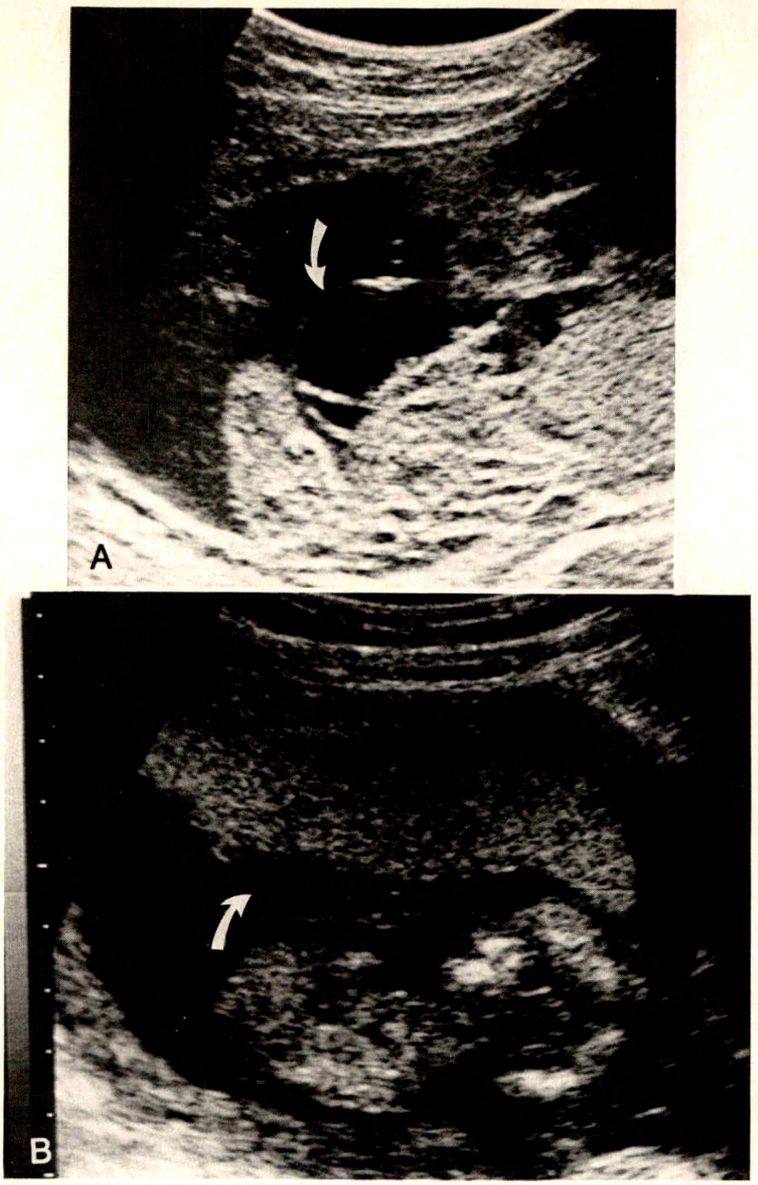

Fig. 1. A and **B**, Ultrasonograms of subchorionic placental lucencies. *Arrows* point to subchorionic lucencies.

population. Thus this ultrasonographic finding does not seem to be associated with elevated maternal serum α-fetoprotein levels. Detailed ultrasonographic and/or perinatal consultation does not appear to be necessary for subchorionic placental lucencies provided the following criteria are met: The lucencies do not appear to have flow within them as seen with chorioangiomas, and there are no associated fetal anomalies or other placental abnormalities identified at the time of ultrasonographic evaluation.

The transverse cerebellar diameter in the second trimester is unaffected by Down syndrome

Lyndon M. Hill, MD,[a] Dawn Rivello, RDMS,[a] Carol Peterson, RDMS,[a] and Sandra Marchese, MS[b]

Pittsburgh, Pennsylvania

Cerebellar hypoplasia is a consistent finding in necropsy studies of children and adults affected by Down syndrome. The transverse cerebellar diameter was measured in 23 second-trimester fetuses with Down syndrome. All the measurements were within the normal range for gestational age. (AM J OBSTET GYNECOL 1991;164:101-3.)

Key words: Transverse cerebellar diameter, Down syndrome

Advanced maternal age is by far the most frequently given indication for genetic amniocentesis. However, <20% of children with Down syndrome are born to women over 35 years of age.[1] Consequently, the use of maternal age alone is an extremely ineffective screening tool. Merkatz and coworkers[2] were the first to discover an association between low maternal serum α-fetoprotein levels and chromosomal aneuploidies. Corroboration of their findings by others,[3, 4] resulted in the current practice of adjusting a patient's risk of having a child with Down syndrome according to maternal age and maternal serum α-fetoprotein level. Unfortunately, this technique has a low sensitivity (13% to 32%) and a high false-positive rate (4.1% to 9%).[3, 5]

As the resolution of ultrasonographic equipment continues to improve, increasingly finer anatomic detail can be appreciated. The growth patterns of different fetal parts have been documented. Hence, deviations in fetal growth, both in the time of onset and in degree, can be documented through serial ultrasonography. With this information, chromosomal or physical abnormalities that affect fetal growth can be detected.

The central nervous system of children and adults with Down syndrome has been extensively evaluated. The abnormalities that have been identified are varied and inconstant. However, Davidoff[6] in an autopsy study of 10 cases of Down syndrome consistently found a small cerebellum. Therefore we sought to evaluate the transcerebellar diameter in fetuses with Down syndrome to determine whether there is a reduction in cerebellar size by the second trimester of pregnancy.

From the Departments of Ultrasound[a] and Human Genetics,[b] Magee-Womens Hospital, University of Pittsburgh.
Received for publication June 28, 1990; revised August 6, 1990; accepted August 15, 1990.
Reprint requests: Lyndon M. Hill, MD, Magee-Womens Hospital, Forbes Ave. and Halket St., Pittsburgh, PA 15213.
6/1/24744

Material and methods

We retrospectively ascertained all women with a gestational age between 15 and 20 weeks who had undergone a level II ultrasonographic examination and genetic amniocentesis at Magee-Womens Hospital between February 1987 and November 1989.

The following dating criteria were required to enter the study: regular menses, no oral contraceptives for 3 months before conception, an early pregnancy test, and a first examination at or before 10 weeks' gestation. Exclusion criteria included insufficient dating parameters, an intrauterine fetal death before the ultrasonographic examination, or failure to image and measure the transverse cerebellar diameter.

Of the 28 fetuses with a karyotypic diagnosis of Down syndrome, 23 met the entrance criteria. All the pregnancies were terminated after a diagnosis of Down syndrome was made.

A thorough ultrasonographic examination was performed with a linear-array real-time system with a 3.5 or a 5.0 MHz transducer (General Electric RT 3000, RT 3200; General Electric Corporation, Milwaukee, Wis.). A composite assessment of gestational age was obtained from standard biometric measurements of the biparietal diameter, femur length, head circumference, and abdominal circumference. The amount of amniotic fluid and the placental site were documented.

We have consistently measured the transverse cerebellar diameter as part of our routine anatomic survey since 1986. A slight posterior angulation from the level of the biparietal diameter permits visualization of the cerebellum (Fig. 1).[7] Hence, whereas we retrospectively accumulated our study group, the transverse cerebellar diameter was measured prospectively. The normal cerebellar diameter for our population as a function of gestational age was derived prospectively from 296 normal pregnant patients with the noted dating criteria

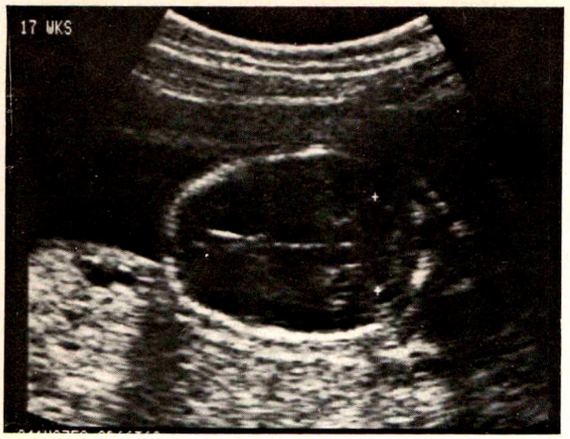

Fig. 1. Graticules outline transverse cerebellar diameter at 17 weeks' gestation.

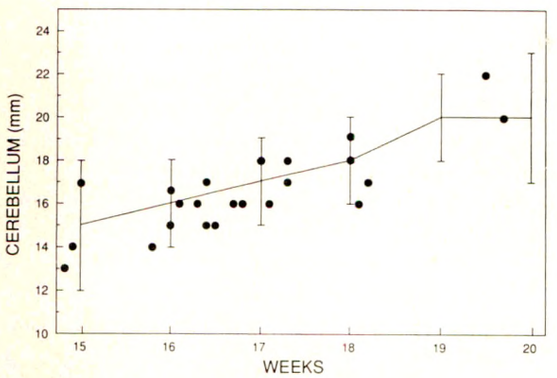

Fig. 2. Normal (± 2 SD) transverse cerebellar diameter from 15 to 20 weeks' gestation. *Filled circles* represent fetuses with Down syndrome.

between 15 to 20 weeks' gestation. Each fetus provided a single data point for the reference curve.

Results

The mean cerebellar diameter (± 2 SD) between 15 and 20 weeks' gestation is presented in Fig. 2. The 23 cases of Down syndrome are also plotted in Fig. 2. It can be seen that the transverse cerebellar diameter is unaffected by Down syndrome in the second trimester.

Comment

Advanced maternal age and decreased maternal serum α-fetoprotein levels are accepted risk factors for Down syndrome. In 1981, approximately 20% of Down syndrome cases were associated with a maternal age >34 years.[1] As women continue to delay child bearing into their midthirties to late thirties, the percentage of Down syndrome newborns will increase.

A second-trimester ultrasonographic examination is not a routine part of antenatal care in the United States. However, it has been estimated that in an average practice, approximately 60% of the patients will require an ultrasonographic examination on the basis of history or physical examination at some point in their pregnancy.[8] The use of ultrasonography in obstetrics will only continue to increase in the future. Hence, the determination of any reliable ultrasonographic signs for Down syndrome might have widespread application.

The finding of a normal transverse cerebellar diameter in fetuses with Down syndrome during the second trimester appears to be at odds with the significantly smaller cerebellar weight found in children and adults with Down syndrome. This paradox can be explained by the time period during which cerebellar development is affected. The two major periods of cellular multiplication in the human brain are from 15 to 20 weeks and from 25 weeks until 2 to 4 years of age. The first phase of multiplication represents proliferation of neuroblasts, whereas the second phase is primarily concerned with glial division and neuroblast maturation.[12] The neuroblasts differentiate into interstitial neurons, Golgi cells and Purkinje cells. Although the Purkinje cells obtain their full number at birth, they are immature and undeveloped. The subsequent differentiation of the Purkinje cells during childhood plays a major role in the development of the cerebellum. Cerebellar hypoplasia may result if this process is inhibited.[13] Degenerative processes after birth also appear to play a role in the reduction of brain size that has been consistently noted with Down syndrome.[10]

In conclusion, cerebellar hypoplasia in neonates and adults with Down syndrome appears to occur after the second trimester. Consequently, measurement of the transverse cerebellar diameter before 20 weeks' gestation cannot be used as an ultrasonographic sign for the detection of Down syndrome.

Maternal postprandial glucose levels and infant birth weight: The Diabetes in Early Pregnancy Study

Lois Jovanovic-Peterson, MD,[a] Charles M. Peterson, MD,[a] George F. Reed, PhD,[b] Boyd E. Metzger, MD,[c] James L. Mills, MD, MS,[b] Robert H. Knopp, MD,[d] Jerome H. Aarons, MD,[c] and the National Institute of Child Health and Human Development—Diabetes in Early Pregnancy Study

Santa Barbara, California, Bethesda, Maryland, Chicago, Illinois, Seattle, Washington, and Pittsburgh, Pennsylvania

The cause of macrosomia in the infant of the diabetic woman is still not completely defined. The National Institute of Child Health and Human Development—Diabetes in Early Pregnancy Study, which recruited insulin-dependent diabetic and control women before conception, provided an opportunity to address the relationship between maternal glycemia and percentile birth weight. Data were analyzed from 323 diabetic and 361 control women. Fasting and nonfasting venous plasma glucose were measured on alternate weeks in the first trimester and monthly thereafter. Glycosylated hemoglobin was measured weekly in the first trimester and monthly thereafter. More infants of the diabetic women were at or above the 90th percentile for birth weight than infants of control women (28.5% versus 13.1%, $p < 0.001$). Although first-trimester nonfasting glucose and glycosylated hemoglobin levels were positively correlated with infant birth weight ($p < 0.001$ and $p = 0.008$), when the analyses were adjusted for the variables of the subsequent trimesters the values became insignificant, whereas the third-trimester nonfasting glucose levels adjusted for values in prior trimesters emerged as the stronger predictor of percentile birth weight ($p = 0.001$). After adjusting for maternal hypertension, smoking, and ponderal index, the above relationships remained. In conclusion, monitoring of nonfasting glucose levels rather than the fasting levels, which are more commonly monitored in clinical practice, are necessary to prevent macrosomia. (AM J OBSTET GYNECOL 1991;164:103-11.)

Key words: Type I diabetes mellitus, macrosomia, postprandial glucose, glycosylated hemoglobin, pregnancy

Fetal macrosomia, defined as greater than the 90th percentile for weight, occurs in 25% to 42% of pregnancies in diabetic women as compared with 8% to 14% in control populations.[1] Macrosomic infants of diabetic women suffer increased morbidity and mortality from unexplained death in utero, birth trauma, hypertrophic cardiomyopathy, vascular thrombosis, neonatal hypoglycemia, hyperbilirubinemia, erythrocytosis, and respiratory distress. Therefore inquiries into the nature and causes of macrosomia are important to find means by which many of these complications may be avoided.

The Pedersen hypothesis[2] states that maternal hyperglycemia stimulates the fetal pancreas to secrete excess insulin, which produces *inter alia* adiposity and macrosomia. Although there is increasing evidence that

maternal glucose levels influence fetal growth, there is still controversy as to its importance in causing macrosomia.[3] There is now evidence in support of modifying the Pedersen hypothesis to include additional fuels as causal agents for macrosomia.[4]

On the one hand, there are reports that despite "normoglycemia" macrosomia remains more common in pregnancies complicated by diabetes than in the normal population.[5-7] On the other hand, a number of groups have reported that meticulous efforts to achieve tight control of diabetes can normalize birth weight in infants of diabetic mothers.[8-11] Glycemic control in insulin-dependent diabetic women is particularly difficult to assess. In most prior reports, data are available about glycemic levels in the last half of pregnancy, but lacking in early pregnancy.[12-15] Glycosylated hemoglobin levels provide some information but reflect glucose levels for only the previous 8 to 10 weeks.[16] Furthermore, most studies reflect clinical practice inasmuch as fasting and preprandial glucose values are more often measured than postprandial values.

The National Institute of Child Health and Human Development—Diabetes in Early Pregnancy Study was a multicenter study in which control and diabetic women were recruited before or within 21 days after conception and in which glycemic control was documented by fasting, nonfasting, and glycosylated hemoglobin levels throughout pregnancy.[17] Thus the Diabetes in Early Pregnancy Study provided a unique opportunity to study the relationship between maternal glycemia and infant birth weight.

Methods

The Diabetes in Early Pregnancy Study included Cornell University, Harvard University, Northwestern University, the University of Pittsburgh, and the University of Washington. The National Institute of Child Health and Human Development was the data and coordinating center. The study design has been described in detail elsewhere.[17, 18] When the diagnosis of pregnancy was made, diabetic subjects were hospitalized for 2 to 5 days to monitor metabolic control. Other than reinforcing the techniques of self-monitoring of blood glucose levels and charting the results four times a day (fasting and 1 hour after each meal), a standard approach to the management of diabetes was not imposed; nor were fixed goals for glycemic control mandated. After discharge, diabetic subjects were monitored at weekly clinic visits from weeks 5 through 12 after the last menstrual period and monthly thereafter. At each clinic visit analyses of glycosylated hemoglobin and plasma glucose were performed. Nonfasting glucose was defined as 1 hour after the meal, which represents the highest blood glucose after the meal.[19] Control subjects were screened for gestational diabetes at 26 weeks' gestation according to the criteria establish by the Second International Gestational Diabetes Workshop.[20] Three gestational diabetic women were identified and included in the analysis.

The thiobarbituric acid method was used for glycosylated hemoglobin analysis.[21] This method is not affected by fetal hemoglobin and made it possible to perform all the tests on frozen, washed red blood cells in a single laboratory. Laboratory plasma glucose measurements were performed in each center by an enzymatic method. Although it is acknowledged that routine clinical laboratory analysis of glucose is not always accurate, each center used a certified laboratory and provided unknown samples as spot checks.

The infants' birth weight, gestational age at the time of delivery as determined by four parameters (last menstrual period, basal body temperature charting, ultrasonography at 8 and 12 weeks, and Dubowitz examination of the newborn),[17] gender, and race were used to calculate the infants' percentile birth weight. National natality data were used to construct standards

‡Controlling for second and first trimesters.

for birth weight percentile groups. Race, gender, and gestational age–specific standards were generated from all births in the United States from 1983.[22] Infants were classified into the following percentile birth weight groupings: <3, 3 to 9, 10 to 24, 25 to 49, 50 to 74, 75 to 89, 90 to 96, and ≥97th percentile. Each Diabetes in Early Pregnancy Study subject was then placed in the appropriate percentile group for the analysis. The diabetic and control subjects were compared for demographic, medical, and social factors known to influence the risk of either a small-for-gestational-age or a large-for-gestational-age infant[1] (Table I).

Statistical analyses. Logistic regression for categoric outcomes[23] was used to examine effects of glycemic control (calculated from the mean levels of fasting glucose, nonfasting glucose, and glycosylated hemoglobin for each woman for that trimester). Initially, the effect of glycemic control in each trimester of pregnancy was examined separately. Then, the effect of control in each trimester was examined adjusting for control in prior or subsequent trimesters. A total of 221 diabetic women had fasting glucose determinations for all three trimes-

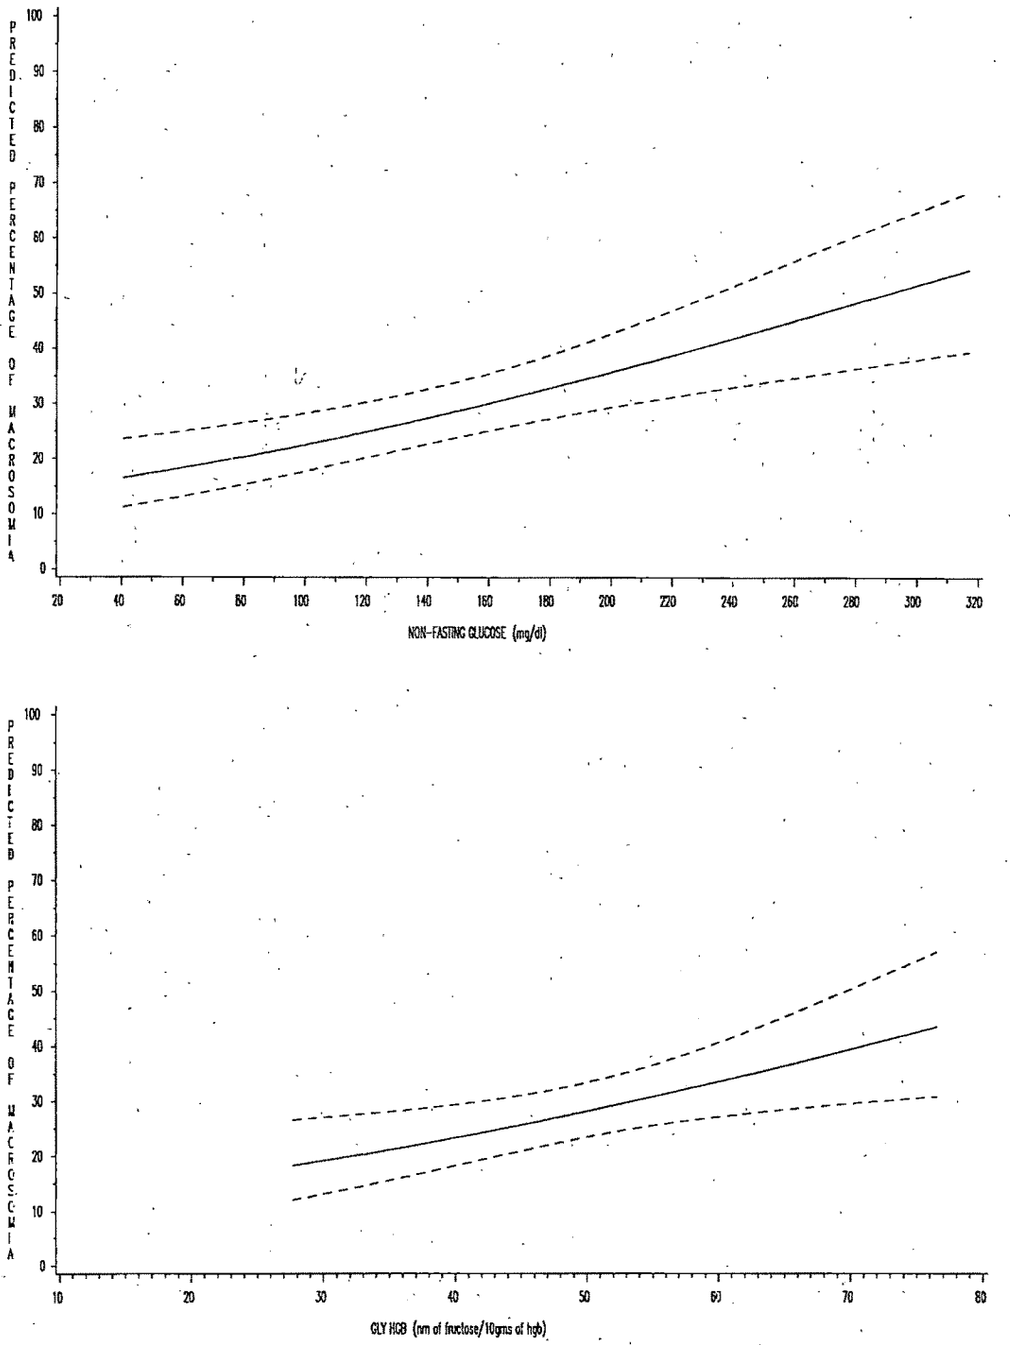

Fig. 1. *Top panel,* Risk of macrosomia (and 95% confidence interval) on basis of first-trimester nonfasting glucose levels in diabetic subjects. *Bottom panel,* Risk of macrosomia (and 95% confidence interval) on basis of first-trimester glycosylated hemoglobin levels in diabetic subjects (normal = mean ± SD = 38 ± 5 nmol fructose/10 gm hemoglobin).

ters; 92 had nonfasting glucose determinations for all three trimesters; and 199 had glycosylated hemoglobin determinations for all three trimesters. To verify that those women who had elevated glucose levels in the first trimester were the same women who had elevated levels in the third trimester, the first and third trimester glucose variables were analyzed by logistic regression.

The regression coefficients corresponding to the

trimester effects are expressed as logarithm odds ratios. A positive value indicates that as the mean glucose or glycosylated hemoglobin increases, then the odds of a birth occurring in a given or higher weight class increases relative to the odds of its occurring in a lower class; a negative value indicates that the odds for being in a higher class decreases in comparison to the odds for being in a lower weight class. Thus significant and

Std Dev, Standard deviation. First trimester: $r = 0.81, p < 0.001$; second trimester: $r = 0.77, p < 0.001$; third trimester: $r = 0.82$, $p < 0.001$.

*Spearman correlation coefficients (glucose hospital levels compared with glucose home levels).

positive coefficients mean that the proportion of births in higher weight classes increases with the independent (glycemic control) variable.

These analyses were then adjusted for five known risk factors for producing either a small-for-gestational-age infant or a large-for-gestational-age infant. They were entered singly because of the relatively small numbers of observations. The five risk factors were as follows: (1) maternal hypertension (blood pressure >140/90 mm Hg) documented at any time during the pregnancy, (2) renal dysfunction as defined as a creatinine clearance <70 ml/min (White class F or RF), (3) maternal smoking during pregnancy, (4) maternal ponderal index (as defined as weight/height × 100) at the first clinic visit after pregnancy was diagnosed (week 5), and (5) maternal weight gain >20 kg by 32 weeks' gestation. Other statistical comparisons were made by the Student *t* test, Spearman correlation coefficients, and Wilcoxon rank sum test. The self-monitored blood glucose results were analyzed in the same fashion as the analysis for the laboratory-determined glucose levels.

Results

The entire data set comprised 323 diabetic and 361 control patients who were delivered of live infants. Table I shows the comparison between diabetic and control groups for maternal height, weight, and age. The diabetic and control mothers were not different for height and weight, but the control mothers were older. Table II shows the distribution of infant percentile birth weight for diabetic and control subjects. Infants of diabetic mothers were in the higher percentiles for body weight. The diabetic group had 92 (28.5%) infants and the control group had 47 (13.1%) infants at or above the 90th percentile ($p < 0.001$).

Table III shows the relationship between the laboratory mean levels of maternal fasting glucose, nonfasting glucose, glycosylated hemoglobin, and the infant percentile birth weight in the diabetic group. The mean of each trimester's variables were analyzed independently. When the fasting plasma glucose level was related to the percentile birth weight, only the second-trimester fasting glucose level showed a significantly positive relationship ($p = 0.024$) (Table IV). The relationship of nonfasting glucose to infant birth weight was significantly positive in each of the three trimesters. The first- and third-trimester nonfasting plasma glucose levels achieved the highest positive significant correlation with percentile birth weight ($p < 0.001$). The relationship between birth weight and level of glycosylated hemoglobin was significant for all trimesters, but the highest degree of significance was seen in the third trimester ($p < 0.001$). Thus when mean values of each trimester were analyzed separately, the first- and third-trimester nonfasting plasma glucose level and the third-trimester glycosylated hemoglobin level emerged with the strongest correlation to subsequent infant birth weight.

Figs. 1 and 2 show the logistic regression of the predicted risk of macrosomia. The top panels use the mean of the diabetic subjects' mean nonfasting glucose levels and the bottom panels use the mean of the diabetic subjects' mean values of glycosylated hemoglobin. As can be seen in Fig. 1, a first-trimester nonfasting blood glucose level >120 mg/dl increases the risk of macrosomia by 24%. Likewise, if the first-trimester glycosylated hemoglobin level is >44 nmol of fructose per 10 gm of hemoglobin (the 95th percentile for the normal control population), the risk of macrosomia is 25%. Fig. 2 shows the mean third-trimester nonfasting and glycohemoglobin values. A mean third-trimester nonfasting glucose level >120 mg/dl increases the risk 23%; similarly a glycohemoglobin level >44 nmol fructose/10 gm hemoglobin increases the risk to 32%.

When the first-trimester mean levels of fasting glucose, nonfasting glucose, and glycosylated hemoglobin were controlled for the values in the second and third trimesters, the effect of the subsequent trimesters eliminated the significant relationship of the first-trimester variables to infant birth weight. This additional analysis diminished the sample size; the women with all three trimester non-fasting glucose levels totalled 92 sets (Table V).

Table VI depicts the results of the analysis when the variables of the second and third trimester were subsequently adjusted for variables in the prior trimester or trimesters. The adjusted second-trimester mean fast-

Median			*Minimum*			*Maximum*		
1	*2*	*3*	*1*	*2*	*3*	*1*	*2*	*3*
125	114	105	19	26	5	554	411	301
113	104	90	9	2	40	400	355	297

ing plasma glucose ($p = 0.035$), the adjusted third-trimester mean nonfasting plasma glucose ($p = 0.009$), and the adjusted third-trimester mean glycosylated hemoglobin ($p = 0.018$) levels showed a significant correlation with infant percentile birth weight. Again, this analysis diminished the sample size.

Table VII shows the data from the self-monitored blood glucose diaries. Because the number of observations in the third trimester was lower than the preceding trimesters, we used the diary data from the third trimester to confirm the relationship between glucose and macrosomia seen in the laboratory values. The same observation was found between the fasting and nonfasting values. It is noteworthy that the correlation between the diary values and the laboratory values was excellent ($r = 0.81, p < 0.001$).

Elevated blood glucose variables in the first trimester did correlate significantly with elevated variables in the third trimester (fasting glucose: $r = 0.43, p = 0.0001$; nonfasting glucose: $r = 0.48, p = 0.0001$; glycosylated hemoglobin: $r = 0.68, p = 0.0001$). Thus it was shown that those women who had elevated glucose variables in the first trimester tended to be the same women who had the elevated variables in the third trimester. It is noteworthy that the normal controls also showed a similar relationship between blood glucose values in the first and third trimester (pooled fasting and nonfasting glucose: $r = 0.53$, $p = 0.0002$; glycosylated hemoglobin: $r = 0.23$, $p = 0.01$), although there was no relationship between the normal controls' parameters of glucose control and their infants' birth weight.

When all the analyses were repeated with adjustment for hypertension, renal dysfunction, smoking, ponderal index, and weight gain, the following observations were made:

1. Sixty-one of 323 women had a blood pressure level >140/90 mm Hg at any time during the pregnancy. Macrosomic babies were significantly less likely to be associated with a high blood pressure ($p = 0.004$) (Wilcoxon rank sum test).

2. Twenty-five of 323 women had renal dysfunction, classified as White class F or RF. The lower birth weight babies were more likely to be associated with mothers who were classified as White class F or RF ($p = 0.001$). Macrosomic infants were significantly less likely to be associated with White class F or RF.

3. Forty-nine of 323 women smoked. There was no association between birth weight groups and smoking (p = NS).

4. There was no association between ponderal index and birth weight groups (p = NS).

5. Fifteen of the 323 women gained >20 kg by 32 weeks' gestation. A weight gain in the mother ≥20 kg by week 32 is more likely to be associated with a high birth weight in the infant. All 15 women who gained ≥20 kg had infants whose birth weight was in the top 50th percentile. Seven of these women (47%) had infants in the top 10th percentile for birth weight, the definition of macrosomia.

Comment

The Diabetes in Early Pregnancy Study undertook a prospective analysis of the relationship between maternal glucose control during pregnancy complicated by diabetes and subsequent percentile birth weight. The data indicate that glycemic control in late pregnancy is the strongest metabolic determinant of birth weight, but there is a major contribution from the nonfasting and glycosylated hemoglobin from both prior trimesters.

If elevated glycosylated hemoglobin levels and macrosomia are each mediated by ambient glucose levels, then the nonfasting plasma glucose level appears to contribute more to both the glycosylated hemoglobin and to the risk of macrosomia than the fasting plasma glucose. Early studies of glycosylated hemoglobin documented that hemoglobin A_{Ic} levels correlated better with the peak plasma glucose or the area under the curve on a glucose tolerance test than with the fasting glucose value.[24] Our study shows that peak glucose levels during the day are more predictive of the infant birth weight than the lowest blood glucose level of the day (the fasting). Our finding that the nonfasting glucose level correlates with infant birth weight is consistent with the Pedersen hypothesis[2] in that glucose is still implicated as a causal factor.

Fetal growth is obviously complex and it is possible that metabolic influences on growth are mediated by growth factors or fuels that were not measured.[4] Perhaps we could have obtained a more detailed assessment of the influence of maternal metabolic control on fetal growth if detailed characterization of additional maternal fuels and direct assessment of fetal β-cell function has been feasible. Furthermore, other factors

have been reported to affect fetal growth (e.g., maternal weight, smoking, renal dysfunction, or hypertension)[13] but controlling for these variables did not appreciably alter the significant correlations we found between maternal glycemic control and infant birth weight.

We were intrigued by the correlations between first- and second-trimester indices of glycemic control with birth weight because adipocyte proliferation and the storage of lipids in the fetus occur primarily in the third trimester. The logistic regression analysis did assign greatest significance to glycemic control in the third trimester, although the analysis did diminish our sample size. This could mean that the correlations we observed with birth weight and glycemic control in the first and second trimesters were merely a reflection of the fact that glycemic control was strongly intercorrelated throughout gestation. However, early and late metabolic events may be linked by other mechanisms as well. Thus insulin has been detected in the human fetal pancreas by 10 to 12 weeks[25] and in fetal blood by 11 weeks.[26] Secretion of insulin has been observed in vitro in response to ionic and metabolic stimuli with islets or pancreatic tissue from fetuses in the late phase of the first and early phase of the second trimester.[27, 28] Furthermore, pancreases from fetuses of diabetic mothers have increased β-cell mass and secrete more insulin in vitro[29] by 20 weeks' gestation compared with those from nondiabetic mothers. Thus it is possible that the magnitude of hyperglycemia during early and midgestation may influence the extent of β-cell hyperfunction in later pregnancy and set the stage for the development of macrosomia in the face of continuing hyperglycemia in the third trimester.

Regardless of the mediating factors, our data also indicate that monitoring only fasting and premeal glucose concentrations, which reflect the lowest glucose levels of the day, does not provide an adequate indication of overall metabolic control and the risk of macrosomia. If women with diabetes who are at risk of macrosomic infants are to be identified early and have their treatment altered to improve metabolic control, optimum surveillance should include measurements of glycosylated hemoglobin and nonfasting (postprandial) blood glucose concentrations throughout gestation.

We thank Bruce Ellis and Mary Conley for their statistical expertise. This article is dedicated to the memory of Ms. Anne Duckles, RN, MS, coordinator of Center I.

Association between hypothermia and mortality rate of premature infants—Revisited

Joëlle Hazan, MD, Urs Maag, PhD, and Philippe Chessex, MD
Montreal, Quebec, Canada

The incidence of hypothermia (axillary temperature <35° C) on admission of an infant to a neonatal intensive care unit was retrospectively analyzed in 559 very-low-birth-weight (<1500 gm) newborn infants. The smaller infants were at greater risk of hypothermia. Only in the larger neonates was mortality related to hypothermia, which suggests that this known association bears little cause-effect relationship. (Am J Obstet Gynecol 1991;164:111-2.)

Key words: Prematurity, body temperature, hypothermia, mortality

Very-low-birth-weight preterm newborn infants are prone to thermoregulatory problems because they have important sources of heat loss coupled with a limited supply of brown fat for nonshivering thermogenesis. Alterations in temperature homeostasis can have serious consequences on the mortality rate of preterm infants.[1] With the survival of smaller infants, it was deemed of interest to evaluate the incidence of hypothermia on admission, as an indicator of the quality of perinatal care.

Methods

Appropriate-for-gestational-age inborn and outborn infants weighing between 750 and 1500 gm, who were admitted to the Neonatal Intensive Care Unit of Hôpital Sainte-Justine during two 2-year periods (1980-1981 and 1984-1985) entered this retrospective study. An analysis of the infant's chart was conducted to evaluate axillary temperature on admission, duration of hospitalization, and survival rate. Hypothermia was defined a priori as a temperature <35° C. Duration of hospitalization was defined as the total number of days spent in the unit before death, discharge, or retransfer to the referring hospital. Infants transported after 12 hours of age, as well as stillbirths and infants with chromosomal anomalies or malformations, were excluded. The population was divided into three subgroups according to birth weight: group 1, 750 to 999 gm (n = 128); group 2, 1000 to 1249 gm (n = 172); group 3, 1250 to 1500 gm (n = 259).

In the delivery room, inborn infants were placed under a radiant heater, on a warm sheet, until the skin was dried thoroughly. After resuscitation, the neonates were transported for stabilization to the neonatal intensive care unit, adjacent to the delivery room. The outborn infants were transported by a team consisting of one neonatal nurse and one respiratory therapist. Before transport, the infant's condition was assessed; resuscitation and stabilization procedures were carried out in the referring hospital. The temperature of the transport incubator (model TI100, Air Shields) was preset according to the infant's birth weight: 750 to 999 gm, 40° C, 1000 to 1249 gm, 38° C, 1250 to 1500 gm, 36° C. On admission in the neonatal unit, axillary temperature was measured by the nurses with a mercury thermometer to the closest 0.1 ° C. Axillary instead of rectal temperature was monitored to avoid trauma.

Statistical comparisons were performed by Student's t test for the parametric measurements; differences in frequencies of observations were analyzed by χ^2, with

Table I. Incidence of hypothermia (temperature <35° C) among survivors and deceased infants

Group	n	Hypothermia	Hypothermia among survivors		Hypothermia among deceased infants	
			No.	%	No.	%
750-999 gm	128	30	13/61	21	17/67	25
1000-1249 gm	172	20	11/138	6	9/34	26*
1250-1500 gm	259	16	9/227	4	7/32	22*

*$p < 0.01$ for comparison of incidence of hypothermia between survivors and deceased infants.

Yates' correction for continuity. Incidences of hypothermia were compared between survivors and deceased infants for the entire populations (750 to 1500 gm) of inborn and outborn infants. For multiple comparisons the Bonferroni method was used. A probability value <0.05 was considered significant.

Results

The birth weights, gestational ages, and Apgar scores at 5 minutes were not significantly different between the inborn and outborn populations. Those infants in the smallest birth weight group (750 to 999 gm) had the lowest ($p < 0.01$) temperature on arrival in the unit, in the outborn as well as the inborn populations (mean ± SD 35.1° ± 0.8° and 35.3° ± 0.9° C), compared with the 1000 to 1249 gm group (35.8° ± 0.8° and 35.5° ± 0.7° C), as well as with the 1250 to 1500 gm newborn infants (36.0° ± 0.9° and 35.7° ± 0.6° C).

There was no difference in the incidence of hypothermia between 1980-1981 and 1984-1985. Therefore data on hypothermia for those two periods were combined. Furthermore, there was no difference between inborn and outborn populations in the overall incidence of hypothermia (47/407 or 11.5% vs 19/152 or 12.5%) or in the incidence of hypothermia among survivors (25/312 or 8% vs 8/114 or 7%) or deceased infants (25/95 or 23% vs 11/38 or 29%). Therefore both populations were combined in Table I. The incidence of hypothermia was statistically greater ($p < 0.001$) in the smallest infants (30/128 or 23%) compared with the 1250 to 1500 gm group (16/259 or 6%). Except for the infants in the smallest birth weight group, hypothermia was significantly more frequent in the subgroup of infants who died. Hypothermia did not affect the length of hospitalization (750 to 999 gm, 97 ± 31 vs 89 ± 43 days; 1000 to 1249 gm, 59 ± 19 vs 60 ± 34 days; 1250 to 1499 gm, 41 ± 12 vs 44 ± 29 days).

Comment

Cold stress or hypothermia has been reported for rectal temperatures ranging from 32° to 36° C. Mortality among premature infants has been shown to be significantly greater when rectal temperature on arrival in the hospital was <34° C.[2] In this study a similar association was found in the larger infants despite a higher axillary temperature (<35° C); axillary temperature has been shown to correlate closely with rectal temperature.

Although larger newborn infants are able to react to a cold stimulus by increasing metabolic rate, it is hardly surprising that the sicker preterm infants do not have temperature regulated as well and that consequently neonatal mortality could be related to hypothermia on arrival in the hospital. However, numerous confounding factors could account for the fact that this is merely an association, with little cause-effect relationship. Indeed such an association was not found in the smallest infants (<1000 gm), who had the lowest mean temperature and the highest incidence of hypothermia on arrival in the unit. This could be explained by the fact that the thermogenic capacity of the very small premature infant, whether sick or not, can be rapidly insufficient to prevent a fall in body temperature. Therefore in the smallest preterm infants one has to be careful about attributing poor neonatal outcome to hypothermia on admission to the nursery.

Burlington and Hamilton, Ontario, Canada

The accuracy of clinical diagnosis for pelvic inflammatory disease was determined in 95 women who presented with pelvic pain to primary care physicians and then were referred to gynecologists. Laparoscopy or laparotomy with endometrial biopsy and fimbrial minibiopsy revealed that prevalence of pelvic inflammatory was 46% (44/95) and positive and negative predictive values of gynecologists were 74% (23/31) and 67% (43/64) ($p = 0.0002$). If histopathologic diagnosis was the standard, clinical accuracies of the gynecologists were no better than chance ($p = 0.43$), suggesting an expectation bias for visual diagnosis. Laparoscopy had a sensitivity of 50% (12/24) and a specificity of 80% (40/50) for salpingitis if the standard was fimbrial histopathologic diagnosis ($p = 0.01$). These results support the routine use of laparoscopy, supplemented when negative by endometrial and fimbrial minibiopsy, to accurately diagnose pelvic inflammatory disease. (Am J Obstet Gynecol 1991;164:113-20.)

Key words: Pelvic inflammatory disease, laparoscopy, diagnostic errors, biopsy, routine diagnostic tests

Jacobson[1] was the first to measure the accuracy of clinical diagnoses in women hospitalized for pelvic pain. The positive predictive value of a clinical diagnosis of salpingitis was 70% and the negative predictive value of other clinical diagnoses was 79% when the standard of diagnosis was laparoscopy or laparotomy. Clinical signs of salpingitis such as cervical motion and adnexal tenderness have been evaluated for sensitivity and positive predictive value[1-3] but not for their specificity and negative predictive value. The probability of disease in a patient cannot be estimated without knowledge of the specificity of a sign, even if the sensitivity and prevalence of disease are known.[1] A final concern is the adoption of laparoscopy as the diagnostic standard of salpingitis without validation.[5]

Much research has been done on women hospitalized with suspected pelvic inflammatory disease despite the fact that most cases are managed outside of hospitals.[6] We analyzed the clinical, laboratory, operative, and histopathologic findings of women who presented to primary care physicians because of pelvic pain.

Material and methods

Sample. In Burlington, Ontario, consecutive women with pelvic pain, presenting to 65 family physicians and the six casualty officers at the emergency department of the hospital, were referred to one of three gynecologists for laparoscopy or laparotomy if the primary care physician considered the pain to represent pelvic inflammatory disease or another important condition (e.g., ectopic pregnancy, appendicitis). Diagnoses were made as usual and there were no preset criteria insisted on for the diagnosis of pelvic inflammatory disease (see Comment). Primary care physicians and gynecologists were allowed to use any diagnostic tests available to them before they recorded their preoperative diagnoses. Eligibility criteria were that the women had to be premenopausal and not known to be pregnant, no antimicrobial treatment, abortion, or abdominal surgery had occurred in the previous 6 weeks, the uterus and at least one fallopian tube had to be present, the pain had not been present for more than 2 months, and they had to be fit for surgery. Of the 95 women who signed a consent form approved by the McMaster University Ethics Committee and underwent surgical exploration, 63% presented to the primary care physician in the office, 33% came to the emergency department and 4% were seen on the wards. Pelvic pain was assessed as mild, moderate, or severe in 3%, 63%, and 34%, respectively, and the mean ± SD delay from

patient entry to operation was 1.7 ± 5.2 days. Another 44 women (one of whom refused to give consent) were thought by the gynecologist not to have serious pathologic conditions, were not entered, and were observed only.

Operative procedure. With the patients under general anesthesia, a sample of vaginal fluid and four endocervical swabs were obtained for microbiologic studies. After the cervix had been cleansed with povidone-iodine solution, biopsy of the endometrium was performed with a Novak suction curette in 92% (87/95). Laparoscopy (carbon dioxide pneumoperitoneum with the two-puncture technique), laparotomy, or both were carried out in standard fashion in 73, 14, and 8 patients, respectively. Fimbrial minibiopsies (approximately 1 mm^3) were done with laparoscopy scissors in 78% (74/95). Three endotubal swabs were obtained or a fallopian tube was aspirated as previously described,[7] and a sample of cul-de-sac fluid was aspirated for bacteriologic studies. The gynecologist recorded the operative findings and postoperative diagnosis.

Laboratory methods. Bacterial vaginosis was diagnosed from vaginal fluid if at least three of four signs were present (thin and homogeneous appearance, pH >4.5, smell of volatile amines after the addition of 10% potassium hydroxide, or presence of clue cells on wet mount examination) or if a Gram-stained smear showed typical changes.[8] Endocervical swabs were inserted serially and rotated to obtain samples in the following order: the first for *Neisseria gonorrhoeae* culture[9] and detection of purulent cervicitis[10] and intracellular gram-negative diplococci on Gram-stained smear, the second for aerobic[11] and anaerobic[12] cultures, the third for mycoplasma cultures[13] (*Mycoplasma hominis* and *Ureaplasma urealyticum*), and the fourth for *Chlamydia trachomatis* by cell culture[14] (after cervical mucus had been removed with a cotton swab). Similarly, aspirates of cul-de-sac fluid and the three endotubal swabs were cultured for *N. gonorrhoeae,* aerobes, anaerobes, mycoplasmas and *C. trachomatis*. Specimens were inoculated in the operating room to optimize sensitivity of the bacteriologic methods. After inoculation anaerobic plates were placed in the Marion Bio Bag (Nordic Scientific, Kirkland, Quebec) anaerobic transport system and transferred into the anaerobic chamber without opening the Bio Bag container.

Midstream urine samples were sent for urinalysis, culture, and testing (sensitivity 500 IU/L) for human chorionic gonadotropin β-subunit (β-hCG) (Neo Planotest Duoclon, Organon Teknika, Scarborough, Ontario). Preoperative blood samples were obtained for complete blood count, erythrocyte sedimentation rate, C-reactive protein,[15] (normal value <18 mg/L), and radioimmunoassay for β-hCG[16] (positive, >5 IU/L). Results of these tests were not available preoperatively unless an attending physician had ordered them. In preoperative and convalescent (2 months after operation) serum samples, *C. trachomatis* immunoglobulin G antibody was measured by the microimmunofluorescence technique of Wang et al.[17] and the criterion for a serologic diagnosis of chlamydial infection was seroconversion or a fourfold or greater change in titers. Preoperative sera were screened for immunoglobulin A antibody to *C. trachomatis* by a slide immunoperoxidase test (Ipazyme; Sargon Diagnostics, Ltd; Ramat Gan, Israel) with a single dilution of 1:16. Biopsy specimens were fixed in 10% formalin and paraffin-embedded sections were stained: one from each patient by hematoxylin and eosin and one with the methyl green-pyronin method for plasma cell identification.[18]

Definitions of pelvic inflammatory disease, endometritis, and salpingitis. Pelvic inflammatory disease was assessed by either visual signs of salpingitis or histopathologic evidence from fimbrial or endometrial biopsy specimens (ALL-PID) or, alternatively, by histopathologic evidence only (PATH-PID). The minimal signs for a gynecologist to make a visual diagnosis of salpingitis were abnormal erythema and edema of the fallopian tubes. The presence of spontaneous or expressible inflammatory exudate from the fallopian tube(s) was not a prerequisite if the gynecologist thought that salpingitis was definitely present visually. Bacterial growth from an upper genital tract specimen was never present without visual and histopathologic evidence of salpingitis. Tissue sections were examined independently by three pathologists who were given only the patient's age and number of days since her last menstrual period. To avoid overdiagnosis of endometritis and salpingitis, a consensus was necessary among the three pathologists that plasma cells, lymphoid aggregates (perivascular or subepithelial), or polymorphonuclear leukocytes in the tissue sections were diagnostic of pelvic inflammatory disease. Inflammation was graded as acute if there was a predominance of polymorphonuclear leukocytes and chronic if plasma cells or lymphoid aggregates prevailed. Subacute inflammation showed both acute and chronic features. Plasma cells were seen in 88% (15/17) of sections showing endometritis and 75% (18/24) of those showing salpingitis. To test the validity of histopathologic diagnosis as a criterion, observer agreement studies with the three pathologists were conducted on a random (with a random number table) sample of half of the endometrial and fimbrial sections. Between pairs of pathologists, simple agreement varied from 80% to 91% and agreement beyond that due to chance (κ coefficient[19]) varied from 0.49 to 0.80, indicating fair to excellent agreement.[20]

Statistical methods. We chose a clinically impor-

tant difference (positive predictive value minus false-negative rate) of 30% for the purpose of sample size estimation. If the difference was found to be ≤30%, there was definite cause for concern about the ability of clinical examination to detect pelvic inflammatory disease. A significance level, α, was chosen to be 0.05 (one-tailed) and the probability of a type II error, β, was chosen to be 0.10 with a χ^2 test. A sample size of 95 women sufficed since recruitment ratios for the clinical diagnoses of non–pelvic inflammatory disease/pelvic inflammatory disease were 45:50 and 64:31 for primary care physicians and gynecologists. Clinical accuracy was calculated by dividing the sum of the true-positive and true-negative results by the total number of patients. Since there were repeated measurements (two) on each of the patients, one by a primary care physician and another by a gynecologist, McNemar's test (with Yates' correction) for matched pairs was used to compare primary care physicians with gynecologists. Two-tailed p values were computed and denoted significant if they were $<\alpha$. The χ^2 statistic with Yates' continuity correction or Fisher's exact test was used to assess the significance of any associations. Power estimates for nonsignificant differences were from standard tables.[21] The optimal IgG antibody titer for prediction of pelvic inflammatory disease was determined from a receiver-operating-characteristic curve.[4]

Results

Accuracy of clinical diagnosis. The diagnostic performances of gynecologists and primary care physicians, shown in Table I, were no better than those achievable by chance alone, except when gynecologists were compared with ALL-PID (p = 0.0004). The poor performances of the clinicians are probably not due to inadequate sample size since the statistical power of this study to detect a clinical accuracy of 85% (78/92) for PATH-PID by gynecologists, instead of the observed 60% (55/92), was 0.97 (one-tailed α = 0.05) (for this calculation accuracy is the sum of true-positive and true-negative values divided by total number of patients). Among the 95 women assessed with ALL-PID used as the standard of positivity, there were 23 true-positive clinical diagnoses by gynecologists. The false-negative clinical diagnoses by gynecologists were: tubal pregnancy (n = 5), no cause found (n = 4), ovarian cyst (n = 4), hemorrhagic corpus luteum cyst (n = 2), endometriosis (n = 2), appendicitis (n = 2), pyelonephritis (n = 1), and irritable bowel syndrome (n = 1). Of the eight women with false-positive clinical diagnoses of pelvic inflammatory disease, no cause was found in five and endometriosis was diagnosed in three. Women with true clinically negative results had the following final diagnoses: no cause found (n = 19), ovarian cyst (n = 9), appendicitis (n = 5), tubal pregnancy (n = 3), endometriosis (n = 3), irritable bowel syndrome (n = 1), Crohn's disease (n = 1), retrograde menstruation (n = 1), and pelvic congestion syndrome (n = 1). In conjunction with confirmed pelvic inflammatory disease two women had periappendicitis[22] and two others had perihepatitis.[23]

For each case the clinical diagnoses of primary care physicians and gynecologists were compared by matched pair analysis on sensitivity, specificity, positive predictive value, and negative predictive value (Table II). The only significant differences were in specificity and negative predictive value, with gynecologists being superior.

Histopathologic and visual diagnosis of pelvic inflammatory disease. With additional evidence from endometrial and fimbrial biopsy specimens in women with negative visual findings, the prevalence of confirmed pelvic inflammatory disease increased from 30% (28/95) with visual diagnosis alone to 46% (44/95). The diagnostic performances of visual signs and endometrial biopsy are shown in Table III. Endometrial biopsy findings were positive in one third of women with confirmed salpingitis and four patients with pelvic inflammatory disease had endometritis without salpingitis. Compared to fimbrial minibiopsy, visual diagnosis (by

*From χ^2 test.

†85% (81/95) of women were assessed by laparoscopy, and 15% by laparotomy.

‡Statistically significant.

laparoscopy in 85% of patients) missed half of those with histopathologically confirmed salpingitis. Chronic and acute salpingitis was present in 83% (20/24) and 17% (4/24), respectively, of the positive fimbrial minibiopsy specimens. Endometrial histologic examination showed subacute inflammation in 82% (14/17) and chronic inflammation in 18% (3/17).

The confirmation rates by fimbrial histopathologic diagnosis for groups of laparoscopic visual signs are shown in Table IV. Twelve women with only tubal erythema and edema and no purulent exudate would have been negative according to conventional criteria,[2,5] but the rate of confirmation by fimbrial histopathologic diagnosis was the same as for the "mild" category.[5] Eleven other women had laparoscopically negative findings for salpingitis but fimbrial histopathologic diagnosis showed two with acute salpingitis and nine with chronic salpingitis (plasma cells in eight). The laparoscopic criteria recommended by Hager et al.[5] would have missed 58% (14/24) with histologically confirmed salpingitis.

Ectopic pregnancy. Fimbrial histopathologic examination, at a site distant from the ectopic implantation in the seven women with confirmed ectopic pregnancy, showed that three had chronic salpingitis and one had acute salpingitis, which was also visually obvious. Assays for β-hCG in urine and sera had sensitivities for ectopic pregnancy of 43% (3/7) and 100% (7/7), respectively. The five patients in the false-negative category with clinical diagnosis of ectopic pregnancy had salpingitis confirmed by fimbrial histopathologic diagnosis and four of them also had ectopic pregnancy.

Oral contraception and severity of pelvic inflammatory disease. The prevalence of visually mild salpingitis (including those without purulent tubal exudate) or false-negative laparoscopic results (positive

fimbrial histopathologic diagnosis) among women with salpingitis who used oral contraceptives was 79% (11/14) versus 70% (21/30) in all others with salpingitis ($p = 0.42$). The power of this sample size to detect a 40% (12/30) prevalence of less severe disease in those not using oral contraceptives was >0.75 (one-tailed $\alpha = 0.05$).

Predictors of pelvic inflammatory disease. The mean ± SD age of the 95 women was 25.1 ± 6.6 years, 54% were single, and all but one were white. Nulliparous women constituted 58% of the group, 25% were not using contraception, 34% were using oral contraceptives, 8% were using an intrauterine contraceptive device (IUD), and 30% reported IUD use in the past. The mean ± SD age at beginning coitus was 16.8 ± 2.3 years, mean ± SD number of sexual partners in the preceding 12 months was 1.3 ± 0.8, and there was history of sexually transmitted disease and pelvic inflammatory disease in 12% and 30%. A change of sexual partner in the preceding 2 months was reported by 24%. Data on oral sex, douching, and frequency of sexual intercourse were not obtained. All of the demographic, behavioral, clinical, investigational, and operative findings collected by the gynecologists were compared between those with and those without pelvic inflammatory disease to detect significant differences. Variables that had statistically significant associations with the presence of confirmed pelvic inflammatory disease are shown in Table V. There were no significant associations for the rest of the variables, including severity of pain, history of fever, chills, irregular bleeding, urethritis symptoms, nausea, vomiting, diarrhea, increased body temperature, cervical motion tenderness, adnexal tenderness, uterine tenderness, palpable adnexal mass, abnormal vaginal discharge, or presence of bacterial vaginosis or cervicitis (microscopic criterion). The study had a statistical power of at least 0.90 to detect a 30% difference in any of these variables.

IgG antibody to *C. trachomatis* at a titer of ≥1:8 was found in 63% (27/43) of women with ALL-PID and 43% (21/49) of those without ALL-PID ($p = 0.09$) (three acute sera missing). Similarly, IgG antibody was present in 71% (22/31) of women with PATH-PID and 43% (25/58) of those without it ($p = 0.02$). At a dilution of 1:256, 16% (7/43) of those with ALL-PID and none (0/49) of those without it had detectable IgG antibody ($p = 0.004$). Nineteen percent (6/31) of those with PATH-PID and 2% (1/58) of those without it had positive results at a titer of 1:256 ($p = 0.007$). The IgG titer of 1:128 (Table V) was chosen (from receiver-operating-characteristic curves of the dilutions from 0 to ≥1:256) to be the optimal dilution for predicting pelvic inflammatory disease, considering the false-positive and true-positive rates. IgA serum antibodies to *C. trachomatis* were more common in women with pelvic inflammatory disease, whether as ALL-PID ($p = 0.001$) or PATH-PID ($p = 0.03$) (Table V).

Table IV. Visual signs of inflammation and corresponding histopathologic confirmation rates from fimbrial minibiopsies in 39 women with histologic or visual evidence of salpingitis who had laparoscopy performed*

Visual signs†	*Histologically confirmed (%)*	*No. positive/No. biopsies*
Severe	88.9	8/9
Moderate	100.0	1/1
Mild‡	25.0	1/4
Tubal edema and erythema only§	25.0	3/12
Nondiagnostic	100.0	11/11
TOTAL		24/37

*One additional woman with salpingitis had laparotomy only.

†Severe, moderate, and mild refer to laparoscopic classification proposed by Hager et al. whereby severe includes pyosalpinx, pelvic inflammatory complex, or abscess; moderate includes gross purulent material, marked tubal edema, and erythema; and mild includes erythema, edema, and exudate that might require tubal manipulation for expression.

‡Two women with mild salpingitis did not undergo fimbrial minibiopsy.

§No purulent material could be demonstrated with tubal manipulation.

Microbiologic results. *U. urealyticum* was isolated from the endocervix in 48% (21/44) and 28% (14/51) of women with and without ALL-PID ($p = 0.04$). *C. trachomatis* was isolated from the endocervix of 11% (5/44) and 2% (1/51) of those with and without ALL-PID ($p = 0.07$) and *N. gonorrhoeae* from the endocervix of one woman in each group ($p = 1.00$). Recovery of bacteria from fallopian tube or cul-de-sac specimens occurred in 11% (5/44) of patients with ALL-PID: *C. trachomatis* was found in two women who also had positive findings from the endocervix; *Staphylococcus aureus, U. urealyticum,* and an unidentified species of *Eubacterium,* respectively, were found in the other three. Convalescent sera were available from 84% (37/44) of the women with ALL-PID, 10 of whom showed seroconversion or a fourfold or greater change in IgG antibody titers to *C. trachomatis,* versus two of 38 without ALL-PID ($p = 0.01$). Convalescent serum was not obtainable from one of the women whose fallopian tube specimen was positive in chlamydia culture. The prevalence of chlamydial pelvic inflammatory disease, demonstrated by fallopian tube culture or paired serologic test results, was 25% (11/44).

Comment

These results are generalizable to a primary care sample of women with moderate to severe pelvic pain. For

ALL-PID the accuracy of our gynecologists was similar to that found by Jacobson[1] in hospitalized women without benefit of endometrial and fimbrial histopathologic diagnosis. The only statistically significant clinical accuracy, that of gynecologists compared with ALL-PID, may have been due to expectation bias[24] since the same gynecologists performed the visual examinations after their clinical assessments. Logistically, this was unavoidable but we anticipated the potential problem by including blind assessment of histopathologic diagnosis. With PATH-PID the accuracy of gynecologists became similar to that of primary care physicians. The sample size had excellent statistical power to show reasonable clinical accuracies if they existed.

Inadequate criteria for visual and histopathologic diagnoses of pelvic inflammatory disease might be suspected as the reason for poor agreement between clinical, visual, and histopathologic assessments. From experience, our gynecologists felt confident that women with both erythema and edema of the fallopian tubes could have mild salpingitis, despite the absence of tubal exudate. Such women would have been diagnosed as negative for salpingitis by the criteria suggested by Jacobson and Westrom,[2] but they had exactly the same histopathologic confirmation rate as that observed in patients with tubal erythema, edema, and exudate. It appears that the visual diagnosis of mild salpingitis was insensitive if tubal exudate was a requirement. In women without these minimal criteria, false-negative laparoscopic results are an acknowledged problem,[5, 25-27] hypothetically because of endosalpingitis. Resolving clinical disease in which histopathologic resolution is lagging behind is another possibility that may have support, since 9 of the 11 women with negative laparoscopic findings and histopathologic evidence of salpingitis had chronic inflammatory changes. However, laparoscopy often revealed salpingitis or bacteria were cultured from the tubes when there were chronic histopathologic changes; prior antimicrobial treatment was an exclusion criterion and most women had illnesses of short duration. Studies that use second-look laparoscopy and fimbrial minibiopsy would be helpful to settle this question. Laparoscopy was not specific for histopathologic evidence of salpingitis possibly because pathologic involvement of the tissues may not have been homogeneous and biopsies or histologic sec-

tions may have missed the abnormal areas. Serosal hyperemia caused by carbonic acid formation from carbon dioxide pneumoperitoneum or the phase of the menstrual cycle may have contributed to visual false-positive results.

Histopathologic criteria for endometritis and salpingitis that define the necessary numbers of plasma cells or lymphocytes in the stroma and polymorphonuclear leukocytes in the mucosa have not been evaluated in the literature. For this reason a consensus by three pathologists, one of whom was an expert in gynecologic pathology (H.R.), was used to provide an unbiased assessment of PATH-PID. The agreement studies suggested that our pathologists were competent and the histopathologic criteria for PATH-PID gave reproducible results. Other investigators have used fimbrial minibiopsy to detect chlamydial infection. Westrom and Mardh[28] took minute specimens of fimbria for culture without any adverse effect on subsequent fertility. Kiviat et al.[7] detected *C. trachomatis* by immunofluorescence staining of fimbrial biopsy specimens, and at second-look laparoscopy DeWilde[29] reported the absence of new fimbrial adhesions 1 week after biopsies had been performed.

Paavonen et al.[30] reported the sensitivity and specificity of endometrial biopsy were 89% and 67% for laparoscopically confirmed pelvic inflammatory disease in women with clinically suspected disease. Our findings showed that endometrial biopsy was less sensitive but more specific, perhaps because of the inclusion of not only the cohort with other clinical diagnoses but also those with histopathologic evidence of salpingitis.

Inclusion in the study of those at risk for pelvic inflammatory disease, but thought to have other causes of pelvic pain, not only changed the estimate of prevalence of pelvic inflammatory disease and demonstrated that one third of these women with pelvic inflammatory disease would have been clinically missed by gynecologists but also revealed the sensitivities and specificities of risk factors and clinical findings. This was the first determination of specificities, since the report by Jacobson and Westrom[2] did not include women who had the clinical impression of the absence of salpingitis confirmed (true clinically negative). Associations between pelvic inflammatory disease and a shorter duration of pain, a history of abortion or sexually transmitted disease, and current IUD use have been reported previously.[26, 31-33] Svensson et al.[34] found a beneficial association between oral contraceptive use and visually milder disease, which we did not confirm. In agreement with previous reports[2, 35-38] elevated levels of several blood tests (erythrocyte sedimentation rate, C-reactive protein, white blood cell count, and serum IgG and IgA antibodies to *C. trachomatis*) were associated with pelvic inflammatory disease (Table V). Only two clinical signs were significantly associated with pelvic inflammatory disease (Table V), and this supports the role of laboratory tests in the clinical assessment of women with pelvic pain.

Serum β-hCG determination should be an essential part of the clinical workup of women with acute pelvic pain.[16] Although serum β-hCG testing performed better than urine testing, it did not discriminate well between those with pelvic inflammatory disease and those with ectopic pregnancy since the two conditions sometimes coexisted in our patients. Histopathologic evidence of chronic salpingitis at a site away from the ectopic implantation has been reported recently,[39, 40] and there is an association between the presence of chlamydial serum antibodies and chronic salpingitis.[39]

With the use of comparable methods our isolation rates of bacteria from intraabdominal sites were different from those of two recent hospital-based North American and Scandinavian studies of laparoscopically confirmed salpingitis.[41, 42] Brunham et al.[39] and Paavonen et al.[42] reported isolation rates of 42% and 71% overall, 4% and 34% for *C. trachomatis*, 18% and 14% for *N. gonorrhoeae*, and 0% and 3% for both microorganisms. The comparatively few infections by other bacteria may reflect sampling of a primary care population of women with fewer previous episodes of pelvic inflammatory disease and milder infections than those in hospital-based studies. Chlamydial pelvic inflammatory disease was detected by isolation from the fallopian tubes or with paired IgG microimmunofluorescence serologic testing in 25% of our patients compared with 8% in the study by Brunham et al.[41] Kiviat et al.[7] have shown that it may be difficult to culture chlamydia from fallopian tube swabs despite demonstration of its antigen in tubal epithelial cells by direct immunofluorescence.

In summary, we found that the clinical diagnosis of the presence or absence of pelvic inflammatory disease is no more accurate than chance when the standard of diagnosis is PATH-PID. Since laparoscopy was insensitive for salpingitis, fimbrial minibiopsy or empirical treatment for pelvic inflammatory disease in women with a negative visual diagnosis may be warranted. Investigations such as serum β-hCG levels, endometrial biopsy, and levels of serum antibody to chlamydia should improve outpatient management in cases of moderate to severe pelvic pain by selecting those that would probably benefit from treatment, laparoscopy, or observation.

Antiepileptic medication in pregnancy: Late effects on the children's central nervous system development

Michiel C. van der Pol, MD,[a] Mijna Hadders-Algra, MD,[a] Henk J. Huisjes, MD,[b] and Bert C.L. Touwen, MD[a]

Groningen, The Netherlands

In a follow-up study long-term effects of antenatal exposure to two anticonvulsant drugs, phenobarbital and carbamazepine on central nervous system development were evaluated. Children aged 6 to 13 years of epileptic mothers who used phenobarbital (n = 13), carbamazepine (n = 12), phenobarbital plus carbamazepine (n = 12), or no medication (n = 24) during pregnancy were studied. None of the mothers had seizures during pregnancy. A control group carefully matched for confounding variables was selected of children of nonepileptic mothers (n = 61). Minor and major congenital anomalies appeared to be more related to mother's epilepsy than to maternal medication. There were no neurologic differences between the groups. Exposure to phenobarbital was associated with smaller head circumference. An accompanying negative effect of phenobarbital on cognitive development was suggested. Further research on this intriguing phenomenon seems warranted. (Am J Obstet Gynecol 1991;164:121-8.)

Key words: Maternal epilepsy, anticonvulsants, neurologic development, behavioral development, cognitive development

Do antiepileptic drugs taken during pregnancy have a teratogenetic effect on the developing central nervous system? Children exposed to antiepileptic drugs in utero are reported to have developmental delay, subnormal intelligence quotient[1, 2] and language or learning disabilities[3] more often than children of nonepileptic mothers. In children of mothers with a seizure disorder Nelson and Ellenberg[4] found a slightly higher incidence of cerebral palsy and Speidel and Meadow[5] reported a higher frequency of mental subnormality. Other authors found an increase of congenital anomalies[6] and smaller head circumference[2, 7-9] and suggested that this is an effect of exposure to antiepileptic drugs during pregnancy.

The question is whether and to what extent reported abnormalities must be attributed to anticonvulsant therapy or to other factors associated with epilepsy.[10-12] Seizures during pregnancy might be harmful to the fetus (yes[13, 14]; no[15-17]). Epileptic women seem to share a high obstetric risk,[13, 18, 19] a lower socioeconomic status,[15, 20] and higher incidence of family diseases and congenital anomalies[6, 16, 21]; these factors might also have an adverse effect on the offspring.

From the Department of Developmental Neurology[a] and the Department of Obstetrics and Gynaecology,[b] University Hospital.
Supported by a grant of the Praeventiefonds (28-1515). Part of the Research Programme on Pregnancy and Early Development.

Polytherapy often precludes the analysis of the possible adverse effects of single anticonvulsants. We were able to trace the offspring of small groups of epileptic pregnant women who took either no drugs, phenobarbital, or carbamazepine, or both, and to assess offspring's neurologic, cognitive, and behavioral development at 6 to 13 years of age. A control group was matched for perinatal factors and social class. The study was part of a large follow-up project on perinatal relationships in our University Hospital. No excessive deleterious effects are known of either of the antiepileptic drugs studied. Our question was whether mild neurologic, behavioral, or learning problems may be associated with intrauterine exposure. This makes the present study an explorative one.

Subjects and methods

During the years 1973 to 1981, 132 epileptic mothers were delivered of a live-born infant at the Groningen University Hospital. For the present study, infants were selected who fulfilled the following criteria: (1) documentation of maternal epilepsy by a neurologist; (2) antiepileptic medication: none, phenobarbital, and/or carbamazepine; (3) absence of seizures during pregnancy and delivery; (4) no evidence of intrauterine infection or chromosomal abnormalities; and (5) absence of additional drug exposure.

The selection resulted in a study population of 61 children who had received extensive ante- and perinatal care. Four subgroups were distinguished according to specific antenatal drug exposure: children exposed to phenobarbital only (n = 13); children exposed to carbamazepine only (n = 12); children exposed to

the combination of phenobarbital and carbamazepine (n = 12); and children not exposed to antiepileptic medication (n = 24).

Information on type of epilepsy and dosage of drug(s) is given in Table I. There were no differences in classification of the epilepsy between the groups. The dosages of antiepileptic drugs were constant throughout pregnancy, except for four mothers of the combination group, whose therapeutic regimen needed a small adaptation during the first trimester.

Standardized data on the blood levels of the antiepileptic drugs were not available but clinical data showed an efficient seizure-suppressing effect.

Control children of nonepileptic mothers were selected from singletons born in the same period. They were matched for their mother's parity and for birth weight, gestational age, sex, age at follow-up, and social class. Data on matching criteria and some additional obstetric data are shown in Table II.

Four children of the study groups and six control children were lost to follow-up; this was either because of death, emigration, or (parental) refusal to cooperate (Table I). The parents who refused cooperation reported that their child was not handicapped. The children's age at follow-up ranged from 6 to 13 years. The examiner was unaware of to which group a child belonged.

A standardized and age-specific neurologic examination was carried out[22] with special emphasis on the presence of minor neurologic dysfunction. The findings were classified as normal, minor neurologic dysfunctions, or abnormal. Abnormal meant the presence of an overt neurologic handicap, such as cerebral palsy. Minor neurologic dysfunctions indicated the presence of a mild deviation (e.g., in posture, muscle tone, coordination, or fine manipulative ability) not resulting in an overtly handicapping condition. The examination included the assessment of skull circumference, body weight, and height. Dutch growth charts according to Gerver (unpublished observation) were used as standards. Attention was paid to the presence of major and so-called minor physical anomalies. The minor anomalies were scored in accordance with Waldrop[23] with exclusion of the items on hair and occipitofrontal circumference. A score >2 was taken as a cutting point. Data on obstetric condition, neonatal course, and interval complications were available. Special attention was paid to diseases with possible involvement of the central nervous system. Interval complications in the first 2 years after birth were distinguished from those that occurred later on inasmuch as there are indications that the brain is more vulnerable during the former period.[24, 25]

Three short standardized Dutch tests for reading,[26] spelling,[27] and arithmetic[28] were applied. Children who scored in the lowest tenth percentile were regarded as poor performers. Test results of children are lacking if they were too young or too old to be assessed with these tests, leading to different numbers of children at different tests. School career was considered nonoptimal if the child attended a school designed for learning disorders or was not in the appropriate grade for age.

Both parents and teachers completed an identical questionnaire on the child's behavior, consisting of questions put in a comparative way: "all children sometimes are . . ., do you regard your/this child as more . . ., or less . . ., or don't see any difference" (Table III). Although subjective these lists provide information of the perception of behavior in two important daily situations: at home and at school. Data on the child's behavior were also obtained with help of the child behavior check list[29] and the children's behavior questionnaire for completion by teachers.[30]

Socioeconomic status was classified as low, lower-middle, and upper-middle, according to the father's occupation.

The study groups were admittedly small. Therefore besides univariate analysis with χ^2, Fisher's exact test,

Carbamazepine‡	
≤400	*>400*
—	—
3	8
3	9
—	—

and the Student t test, multivariate statistics (logistic regression analysis and multiple regression analysis for dichotomized discrete and continuous dependent variables, respectively) were applied. The latter techniques offer an appropriate method to analyze the individual and aggregate effects of two or more variables on an outcome measure. In the present study drug use (carbamazepine, phenobarbital) and the presence of maternal epilepsy were entered as independent variables. The p values were considered significant when they were <0.05 (two-sided).

Results

No significant differences were found in the occurrence of (minor) neurologic dysfunction, either between the control and study groups as a whole, or between the control and specific drug groups (Fig. 1). Two boys were classified as abnormal. One belonged to the carbamazepine group; he turned out to suffer from tuberous sclerosis. The other boy belonged to the control group; he had mild spastic diplegia. Both of them were excluded from further analysis inasmuch as there was no reason to presume a relationship between the mother's use of antiepileptic drugs and the one child's tuberous sclerosis, whereas in the control child drugs were not present. Inclusion would hamper the possibility to answer our specific question because both children had behavioral and learning problems that were directly related to their neurologic disorders.

The phenobarbital group showed a surplus of poor performers on the arithmetic ($p = 0.02$) and spelling ($p = 0.01$) tests (Table IV). The other measurements of cognitive development (school career and reading) were similar in the five groups. No differences between the control and study groups were found with the child behavior check list (parents) and the children's behavior questionnaire (teachers). The two "comparative" behavioral questionnaires (Table III) revealed no significant group differences for the majority of items. However, some noteworthy differences emerged: the teachers reported an excess of short attention span in the phenobarbital group, and the parents noted short attention span more often in the carbamazepine group (Table V).

To validate the findings and to evaluate potential interaction effects of drug use and epilepsy, logistic regression models were applied. For this purpose the four study groups and the control group were pooled. The association between phenobarbital exposure and spelling problems was found again ($p < 0.05$); carbamazepine exposure was associated with a decrease of behavioral problems at school, but this effect seemed to be neutralized by phenobarbital exposure (interaction carbamazepine × phenobarbital, $p < 0.05$). The presence of epilepsy in the mother was not related to any of the neurologic, behavioral, or cognitive outcome measures in the child.

Weight and height distribution at follow-up were comparable in the groups. However, skull circumference in all children of the phenobarbital group was on or below the fiftieth percentile. In the phenobarbital plus carbamazepine group head size distribution also showed a significant shift to the left (Fig. 2, $p = 0.021$, χ^2 goodness of fit). In the other groups such a shift was not found (Fig. 2). Multiple regression analysis of the skull circumference distribution ($r^2 = 0.11$, $p = 0.005$) revealed a significant negative effect of phenobarbital ($p = 0.002$) and a positive effect of carbamazepine ($p = 0.03$) without an interaction between the two. Epilepsy per se had no effect on head size.

The Waldrop score ranged from 0 to 4. Fifty percent, 45%, 25%, and 45% of the children of the phenobarbital, carbamazepine, combination, and no drug study group, respectively, had a Waldrop score >2, compared with 18% of the control group, indicating that minor physical anomalies were more frequent in children of epileptic mothers than in children of nonepileptic mothers (44% versus 18%, $\chi^2 = 8.59$, $p < 0.01$). Major congenital anomalies occurred four times as often in the infants of epileptic mothers than in infants of nonepileptic mothers, but the difference only approached statistical significance ($p = 0.07$, Table VI). The presence of major or minor anomalies was not related to any of the neurodevelopmental outcome parameters.

No dose-response relationship could be shown in any of the areas investigated, but the dosages were appreciably low, ranging from 50 to 200 mg daily for phenobarbital and from 100 to 900 mg a day for carbamazepine.

Comment

The potential teratogenicity of antiepileptic drugs is a complex problem inasmuch as many confounding factors such as polytherapy, the epileptic disorder itself, seizures, and associated obstetric adversities may be present. Many studies focus on morphologic abnormalities as a consequence of intrauterine drug expo-

sure. Case histories and retrospective studies claim the existence of specific drug syndromes.[6, 31, 32] It has rarely been possible to confirm a relationship between fetal exposure to antiepileptic drugs and congenital anomalies in a prospective design. Several studies indicate that the offspring of epileptic mothers show congenital malformations more often than children of nonepileptic mothers. However, this surplus of malformations is attributed to the presence of the maternal epileptic disorder.[8, 16, 33-35] Our findings corroborate the concept of a probably endogenous origin of congenital abnormalities in children of epileptic mothers rather than a teratogenic cause on the basis of intake of antiepileptic drugs.

The leading question of the present study was not whether fetal exposure to antiepileptic drugs gives rise to morphologic deviations, but whether it might induce functional aberrations, especially of the central nervous system. The majority of the literature suggests an increase of developmental problems such as a developmental delay and mental subnormality in drug-exposed children. Some report a specific drug effect (Hansen et al.,[2] hydantoin; Jones et al.,[32] carbamazepine), others established a negative effect on cognitive abilities of multiple drug therapy.[5] Gaily et al.[36] evaluated intelligence quotient at the age of 5½ years in a group of children prenatally exposed to varying kinds and numbers of antiepileptic drugs (preponderantly phenytoin and carbamazepine). They did not attribute the slight increase of mental deficiency in their study group to fetal exposure of antiepileptic drugs but assumed a genetic connection with the mother's constitution of epilepsy and borderline intelligence.

Our study evaluates possible adverse effects of two specific antiepileptic drugs (phenobarbital, carbamazepine) while controlling for two possible confounders. The influence of maternal epilepsy was assessed by introducing a group of epileptic mothers without drug treatment and a potential disturbing effect of seizures during pregnancy was ruled out by selecting seizure-free cases.

Neither the evaluated drugs nor the maternal epi-

lepsy had an effect on neurologic development, even when special emphasis was put on minor dysfunctions. No effect was found on behavioral development. This is in contrast with reports of Steinhausen et al.[37] and Hättig and Steinhausen[12] who indicated a slight increase of behavioral problems after fetal exposure to antiepileptic drugs. Skull circumference was the only clear-cut drug effect that we could establish; there was a negative association with phenobarbital exposure and, surprisingly, a positive one with carbamazepine exposure. This is in disagreement with Hilesma et al.[7] who found a more pronounced reduction of head size in carbamazepine-exposed children than in phenobarbital-exposed offspring. Deblay et al.[8] found a high rate of small head size in newborns exposed to a variety of antiepileptic drugs, mostly phenobarbital combined with other drugs, during fetal life and reported that the small head circumference was associated with impaired psychomotor development.

In our study the association between drug exposure and cognitive problems was weak, but to the disadvantage of phenobarbital. Our data indicate a counteracting effect of carbamazepine on the negative influence of phenobarbital. Possibly carbamazepine lowered phenobarbital serum levels inasmuch as it is known to induce hepatic enzyme activity. The possible difference in teratogenicity of phenobarbital and carbamazepine is in accordance with results from animal research that indicate phenobarbital should be regarded as a more potent teratogen than carbamazepine.[6]

Animal studies report growth retardation, microcephaly, and long-term effects on learning and behavior as a consequence of antenatal phenobarbital exposure.[38-41] It is possible that by matching our control group for birth weight we partially eliminated a negative influence of phenobarbital. Still mean birth weight in the phenobarbital group was lower than that in the other three study groups, and the difference between the phenobarbital and carbamazepine groups was significantly lower ($p = 0.005$; Table I). The study was not prospectively designed with random assignment of treatment with antiepileptic drugs. Explorative studies such as the present one rarely are. Drug type and dosages were prescribed during prenatal care, guided by the clinical condition. Throughout pregnancy, type and dosages remained constant. Of course the no-medication group comprised patients with a milder type of epilepsy, but in all cases the diagnosis was unequivocal. We did not find any effect of the number of antiepileptic drugs (zero, one, or two) on any of our outcome measures.

Our findings are the more remarkable inasmuch as the dosages of antiepileptic drugs were low, the pregnant women's epilepsy was well controlled, and con-

founders could be eliminated by careful matching. Phenobarbital is a potent neurotropic drug. It is known to produce a withdrawal syndrome in the newborn, and little is known about the late sequelae of withdrawal. When given to infants and preschool children phenobarbital may cause behavioral disturbances such as irritability, hyperactivity, and attention deficit.[42] It is conceivable that phenobarbital has also a neurotropic effect on the developing fetal brain, possibly with long-term consequences.

The offspring of epileptic mothers has a slightly increased risk of developmental anomalies. Part of this risk can be attributed to factors linked with the mother's disorder.

Evidence is gradually accumulating that the use of particular anticonvulsants during pregnancy is not as safe as is usually presumed for an epileptic mother's offspring. The present study adds evidence for a teratogenic effect of phenobarbital on skull circumference and possibly on cognitive development. Because both effects and groups are comparatively small, the findings urge for replication in a multicentered design to acquire a substantial number of cases.

We thank Dr. V. Fidler for his statistical help and Mrs. A.A. Olinga for more than just her technical assistance and her dotting of *i*'s and crossing of *t*'s, and the children and parents for their cooperation.

Multinuclear spermatozoa associated with polyploidy

Firuza R. Parikh, MD,[a] Margaret J. Iannielo, BS,[b] Michael Kashgarian, MD,[b] Alan H. DeCherney, MD[a] and Gad Lavy, MD[a]

New Haven, Connecticut

We are reporting on a possible association between multinucleated spermatozoa and polyploidy after in vitro fertilization. The semen from the male partner of a couple with 40% polyploidy on three in vitro fertilization attempts was examined by light and transmission electron microscopy. In that sample 10% to 12% of spermatozoa demonstrated conjoined or double heads. The significance of these findings is discussed. (Am J Obstet Gynecol 1991;164:128-9.)

Key words: Multinuclear spermatozoa, in vitro fertilization, polyploidy

Polyploidy occurs in 5% to 10% of human ova that are penetrated in vitro. Polyploidy can arise from polyspermy, which is defined as penetration of an oocyte by more than one spermatozoon, or it may result from the fusion of a diploid gamete with a haploid gamete. Diploidy arises from failure of the first or second meiotic division of gametes. Banding techniques have suggested that chromosomal heteromorphism is a possible mechanism of triploidy. A high rate of polyploidy was observed in several in vitro fertilization cycles in the same individual. This phenomenon appeared to be caused by insemination with spermatozoa from a sample that contained approximately 12% multinucleated forms.

Case report

Mr. and Mrs. R.M. were enrolled in the in vitro fertilization program at the Yale–New Haven Hospital for treatment of unexplained infertility. The husband was 43 years old, and the wife was 40 and nulliparous. Both were in otherwise good health. Semen analysis before enrollment showed a concentration of 59 million per milliliter with 15% abnormal forms.

Established protocols were used during in vitro fertilization. Human menopausal gonadotropin was used for ovarian stimulation, followed by administration of human chorionic gonadotropin in the first two cycles; leuprolide acetate; human menopausal gonadotropin and human chorionic gonadotropin were combined for the third. Thirteen ova were obtained by transvaginal aspiration, three each in the first two cycles and seven in the third cycle. They were staged according to the degree of corona dispersion and cumulus expansion. One oocyte was graded as postmature whereas the others were graded as mature. The semen specimen used in the three in vitro fertilization attempts revealed normal concentration and motility parameters. However, morphologic examination revealed a persistent abnormality. Approximately 10% to 12% of the spermatozoa displayed conjoined or double heads on light microscopy. The specimen obtained in the last cycle showed that 36% of the spermatozoa were pyriform or tapering. Each oocyte was inseminated with 0.5 million sperm prepared by the "swim-up" technique. At 16 or 18 hours after insemination the ova were examined for evidence of penetration and the number of pronuclei were noted. In 4 of the 10 eggs that were fertilized, more than two pronuclei were seen. This number is substantially higher than the incidence of polyploidy in

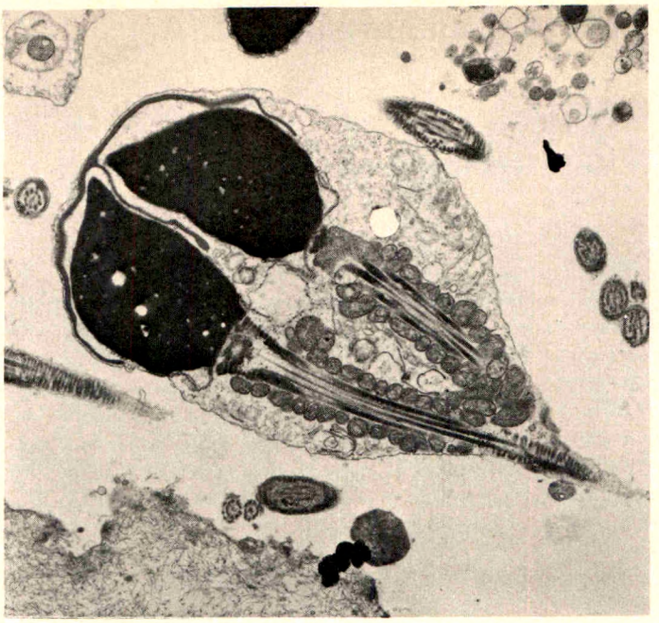

Fig. 1. Electron micrograph of a single-headed, binucleate spermatozoon.

our program (4.7%). None of the ova with polypronuclear development cleaved.

To further evaluate the cause of the high incidence of polyploidy in this couple and because ova appeared normal, the leftover semen specimen from the third in vitro fertilization attempt was examined by light and transmission electron microscopy. On light microscopy conjoined or double heads were found in 10% to 12% of the spermatozoa. Transmission electron microscopy revealed multinucleate heads in 12% of the spermatozoa. Fig. 1 shows a single-headed spermatozoon, but the plasma membrane surrounds two or more clearly individualized nuclei, which share a single acrosome that insinuates the interstices between them. The tail is double, at least in the initial region.

Comment

Utilizing banding techniques, Jacobs et al.[1] showed that 66.4% of 26 triploid spontaneous abortuses were due to dispermy, 23.6% were caused by fertilization of a haploid oocyte by a diploid spermatozoon, and 10% resulted from diploid ova that resulted from failure of the first meiotic division. Diploid spermatozoa are probably the result of failure of the spermatid intercellular bridges to separate. This abnormality is frequently seen after irradiation, and it is sometimes observed in hyperprolactinemia in conjunction with a pituitary tumor. The high incidence of 40% polyploidy together with the finding of 12% multinucleate spermatozoa suggests the latter as a possible cause. Although penetration occurred and resulted in polyploidy in this case, none of the preembryos cleaved, in comparison with the other preembryos that had normal penetration and cleavage.

In summary, electron microscopy was used to document an unusual sperm defect. The presence of multinucleate spermatozoa was associated with and may be related to recurrent polyploidy. In our patient it also helped us to establish that the spermatozoa were not conjoined, which is a rather frequent occurrence, but were multinucleate, which is a rare defect.[2]

Therapy of persistent human papillomavirus disease with two different interferon species

Stanley A. Gall, MD, Lisa Constantine, RN, and Doris Koukol, RN
Louisville, Kentucky

Consensus interferon and interferon alfa-2a were used to treat patients with persistent human papillomavirus disease. Thirty-one patients were treated with either consensus interferon or a placebo (25 received active drug and 6 received placebo), and 24 patients were treated with interferon alfa-2a. Of the 25 patients who received consensus interferon, 19 (76%) showed either complete or partial clearing of condyloma 10 and 16 weeks after initiation of therapy; in 22 of the 24 patients (91%) who received interferon alfa-2a, clearing was demonstrated after a similar time period. Thirty of 34 patients who had no response or a partial response requested additional therapy, and 20 of these patients treated with adjunctive therapy had a complete response. The results of this study support the efficacy of both interferons in the treatment of overt condyloma acuminatum and suggest that interferon enhances subsequent adjunctive therapy. (Am J Obstet Gynecol 1991;164:130-4.)

Key words: Interferon, condyloma acuminatum, interferon alfa-2a, consensus interferon, human papillomavirus

The clinical management of human papillomavirus (HPV) infection of the female genital tract is controversial and nonstandardized because HPV infection is widespread (20% of women are estimated to harbor HPV) and because HPV deoxyribonucleic acid (DNA) is found in most squamous cancers of the female genital tract.[1-5] These two facts intensify the clinical problems that result from the lack of knowledge about the biologic features and natural history of HPV infections. Clinicians are only now realizing that HPV infection usually involves the entire lower female genital tract and that management of subclinical HPV infection is even more controversial than that for overt condyloma.

There is a lack of consensus about the appropriate management of HPV infections in the female genital tract. A recent treatment approach involves the use of interferon, both as primary therapy and as adjunctive therapy. Alpha, beta, and gamma interferons have been reported successful in the therapy of HPV infections.[6-10] The majority of the studies have reported the use of alpha interferon, but the details of dose, dosage schedules, frequency, and route of administration vary considerably.[11] The variety of regimens increases the difficulty of assessing the efficacy of interferon therapy in various stages of HPV disease.

This study was undertaken to assess the effectiveness of two types of interferon in the therapy of resistant and/or persistent HPV infection of the female genital tract. The interferons chosen were consensus interferon (r-Met-Hu IFN-Con) and interferon alfa-2a. Consensus interferon is a product of a synthetic gene for r-Met IFN-Con, which was derived by selecting the most frequently observed amino acid residues at each position of the known members of the interferon family of proteins. Interferon alfa-2a was chosen because it represents a single alpha interferon.[1]

Material and methods

The prospective randomized trial was conducted from 1986 to 1989. Both female patients and one male patient were included in the study only if they had persistent and/or resistant disease. Persistent disease was defined as the presence of HPV manifested as condyloma acuminata for >6 months and 10 or more previous therapies. Therapies could have been podophyllin, trichloroacetic acid or 5-fluorouracil application, surgical removal, fulguration, cryotherapy, or laser therapy. Histologic confirmation of condyloma acuminatum was required. An informed consent form approved by the Institutional Review Committee was signed by each patient who participated in the study. Patients excluded from study included pregnant women or women who were breast-feeding; patients with additional dermatologic disease in the area of condylomas, which could preclude clinical evaluation of the condylomas; patients with granulocyte count $<2000/mm^3$ or platelet count $<100,000/mm^3$; patients with renal dysfunction as measured by a serum creatinine level >1.4 mg/dl; patients with serum glutamic oxaloacetic transaminase >120 U; patients with total

bilirubin level >2.0 mg/dl; patients with symptomatic heart disease, chronic obstructive pulmonary disease, liver disease, malignancy, psychiatric disorder necessitating medication, or any neurologic disorder; patients who were receiving drug therapy for HPV during the prior 14 days; patients with human immunodeficiency virus seropositivity; and patients with evidence of significant immunosuppression as determined by clinical evidence of opportunistic infection or treatment with immunosuppressive drugs.

Patients were prospectively randomized to receive one of five different dosing schedules of consensus interferon or a schedule of interferon alfa-2a. After inclusion in the study, the patients underwent general physical and neurologic examination. The pelvic examination included visual inspection of the perianal area, vulva, vagina, and cervix. Papanicolaou's test and biopsies of genital tract condylomas were done. The vulvar condyloma were documented by recording the bidimensional measurements on a divided grid of the external genitalia. Photographs of the vulva and perineum were made initially and at each subsequent evaluation. Patients were examined at entry and at 2, 4, 6, 10, 14, and 22 weeks during the study. Laboratory evaluations of complete blood count, platelets, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, blood urea nitrogen, and creatinine, as well as lesion measurements and photography, were done at every office visit. HPV DNA typing was not done in this study. Papanicolaou's test was not used to assess response to the interferons.

Consensus interferon was self-administered by intramuscular injection by a protocol that used five different dosing schedules for a 6-week period. These schedules were: schedule 1—high dose, three times per week; schedule 2—low dose, three times per week; schedule 3—high dose, two times per week, and one placebo injection per week; schedule 4—low dose, two times per week, and one placebo injection per week; schedule 5—placebo injection, three times per week. (High dose = 5×10^6 units, or 5 MU; low dose = 2.5×10^6 units, or 2.5 MU; MU = 1×10^6 units.)

The interferon alfa-2a was self-administered intramuscularly at a dose of 3 MU three times per week for 6 weeks, with possible extension of an additional 4 weeks of treatment.

Additional therapy-protocol management decisions were based on global disease assessments as follows: Complete response = total disappearance or clearance of overt warts; partial response = decrease in total wart size by ≥50%. Any change of <50% decrease in wart size was considered nonresponse. Patients were followed up as previously described, and frequently other clinical modalities were used in the nonresponse and partial response categories after the 14-week or 16-week visit.

Symptomatic side effects to interferon treatment which included fever, chills, fatigue, malaise, nausea and vomiting, and headaches, were recorded daily by patients. Clinical laboratory values and side effects were evaluated during each office visit.

Results

Fifty-five patients (54 women and one man) with resistant and persistent HPV infection as manifested by condyloma acuminata were included in this study of the efficacy of interferon therapy. Twenty-four patients received interferon alfa-2a and 31 patients participated in the consensus interferon protocol in which six patients received placebo only. Study participants consisted of 49 white patients, 5 black patients, and 1 oriental patient. Participants ranged from 6 to 50 years (mean, 27.3 years in the interferon alfa-2a group and 28.4 years in the consensus interferon group). One child, age 6, was treated with interferon alfa-2a. All other participants were 18 years of age or older. Baseline characteristics included a mean time of 32.6 months (range, 6 to 240 months) with disease after diagnosis for patients in the interferon alfa-2a group, as compared with a mean of 14.2 months (range, 6 to 24 months) for patients in the consensus interferon group. All female patients included in the study had vulvar lesions that ranged from several small overt condylomas to massive confluent warts. In addition to the vulvar disease found in the interferon alfa-2a group, 10 of the 24 patients (42%) had vaginal condylomas and 6 of the 24 patients (25%) had cervical condylomas. In the consensus interferon group, in addition to vulvar warts, 17 of the 30 patients (57%) had vaginal condylomas and 4 of 30 patients (13%) had cervical condylomas. Also two patients in the interferon alfa-2a group had grade 3 vulvar intraepithelial neoplasia lesions in addition to extensive condyloma. The one male patient had both perianal and penile condyloma.

Thirty-one patients were included in the consensus interferon group, but six patients received placebo only and 25 patients received active drug. The evaluation at 10 weeks after the initiation of the interferon showed that 6 of 25 patients (24%) experienced clearance of disease, 14 of 25 (56%) were partial responders, and 5 of 25 (20%) did not benefit from interferon therapy. When this same group was evaluated at 14 to 16 weeks after the initiation of therapy, 9 of 25 patients (36%) were free of overt disease, 11 of 25 (44%) were partial responders, and 5 of 25 (20%) continued to be nonresponders. The response to individual dosing schedules is shown in Table I. Obviously the number of patients per individual schedule is too small to be significant, but no patient in the placebo group responded and the response in the remaining groups seemed to be similar. Patients received total interferon doses according to schedules as follows: schedule 1, 90 MU;

Table I. Response to consensus interferon by different dosing schedules: Evaluation at follow-up

	10 wk			*14-16 wk*		
	CR	*PR*	*NR*	*CR*	*PR*	*NR*
Schedule 1	1	5	0	2	4	0
Schedule 2	1	4	1	3	2	1
Schedule 3	2	2	2	2	2	2
Schedule 4	2	3	2	2	3	2
Schedule 5	0	0	6	0	0	6

CR, Complete response; *PR*, partial response; *NR*, nonresponse.

Schedule 1: 5 MU t.i.w. × 6 weeks. Schedule 2: 2.5 MU t.i.w. × 6 weeks. Schedule 3: 5 MU b.i.w. and 1 placebo × 6 weeks. Schedule 4: 2.5 MU b.i.w. and 1 placebo × 6 weeks. Schedule 5: placebo t.i.w. × 6 weeks.

schedule 2, 45 MU; schedule 3, 60 MU; schedule 4, 30 MU. The average total dose of interferon was 55.2 MU.

Twenty-four patients were included in the interferon alfa-2a group. Six of 24 patients (25%) in the interferon alfa-2a group experienced clearing of condyloma at the 10-week evaluation, 16 of 24 (66%) were partial responders, and 2 of 24 (8%) experienced no benefit from interferon treatment. Evaluation of this group at 14 weeks showed that 12 of 24 (50%) were complete responders, 10 of 24 (42%) were partial responders, and 2 of 24 (8%) were still nonresponders to interferon therapy. The average total dose of interferon alfa-2a was 88 MU (range of 54 to 216 MU). Seventeen of the 24 patients received interferon alfa-2a after the initial 6-week treatment period. The duration of extended treatment was 2 weeks in 11 patients, 4 weeks in three patients, and 6 weeks in three patients. Of the 11 patients who received an additional 2 weeks of therapy, four patients became complete responders, five patients remained partial responders, and two patients remained nonresponders. Of the three patients who received an additional 4 weeks of interferon, two became complete responders and one remained a partial responder; of the three patients who received an additional 6 weeks of interferon, two remained partial responders and one became a complete responder.

Patients who had completed study protocols were offered adjunctive therapy. The results are shown in Table II. At the conclusion of the study protocol, 21 of 49 patients (43%) who had received interferons experienced complete clearing of lesions, whereas 6 of 6 (100%) who had received placebo showed no clinical benefit. Thirty of 34 patients who had a partial response or no response requested additional therapy. Fifteen patients (50%) received additional interferon, and 5 of 30 patients (17%) were treated with cryotherapy, laser therapy, or surgical excision. Six patients (20%) received either 5-fluorouracil or 85% trichloroacetic acid; four patients (13%) received combination therapy with trichloroacetic acid plus laser, 5-fluorouracil, or cryotherapy or 5-fluorouracil plus trichloroacetic acid. When the efficacy of all adjunctive therapies is reviewed, 20 of the 30 patients (67%) treated were judged to be complete responders 3 months after initiation of adjunctive therapy, eight of the 30 patients (27%) were considered partial responders, and six (20%) patients were lost to follow-up. Four of seven patients treated with interferon who had been nonresponders showed complete response, and three of seven showed a partial response. The adjunctive therapy was successful in the group of six patients who had originally received the placebo. Four of these six patients experienced a complete response, one patient had a partial response, and one patient was lost to follow-up.

Biologic side effects of treatment included fever, chills, fatigue, and malaise in almost all patients at the initiation of therapy. Fever usually occurred only with the first several injections. The most pervasive symptom was fatigue, which continued to some extent in almost every patient until interferon therapy was discontinued. Both consensus interferon and interferon alfa-2a caused similar symptoms, the extent of which was dose-related. Unusual symptoms included weight loss of >10% in one patient and moderate hair loss in two patients. No episodes of leukopenia (≤3000 white blood cells/mm^3) or thrombocytopenia (platelets ≤100,000/mm^3) occurred in any of the patients who had received interferon.

No patient was excluded from the study on the basis of seropositivity. No experience has been obtained in using interferon therapy for treating condyloma acuminatum in patients who are seropositive for human immunodeficiency virus.

Comment

The objective of this research was to determine the efficacy of two different types of alpha interferon. Consensus interferon is a designer molecule produced by *Escherichia coli* through the expression of a synthetic gene that is carried on a plasmid vector. This interferon is different from other alpha interferons in that it consists of an amino acid sequence that reflects the most frequently occurring amino acid residues at each position of the 13 known members of the alpha interferon

Table II. Subsequent therapy after completion of interferon study protocols

Original interferon	n	Final follow-up evaluation at 14-16 wk			Subsequent therapy					3 mo follow-up of subsequent therapy			
		CR	PR	NR	IFN	5-FU or IFN	Cryosurgery or laser	5-FU or TCA	Other*	CR	PR	NR	LTFU
Consensus	25	9	11	5	5	4	1	3	3	11	2	0	3

family of proteins. The 166 amino acid consensus protein has a molecular weight of 19500 d, as do natural leukocyte interferons. The natural subtype interferon F is the alpha interferon that is most closely related to r-Met-Hu IFN-Con_1 (consensus interferon). There are only 10 positions at which consensus interferon differs from interferon F. Comparison of interferon B and consensus interferon shows 57 common amino acid positions. Thus consensus interferon is more similar to beta interferon than to a natural alpha interferon subtype with >30% homology.

One of the first interferons cloned was interferon alfa-2a. This naturally occurring interferon is now mass-produced by recombinant technology that uses *E. coli* to express a gene carried on a plasmid vector. Interferon alfa-2a therapy has been extensively used in clinical trials.

Interferon acts like other cytokines; when it is released into circulation, it interacts with a specific receptor.[12] Alpha and beta interferons appear to have a glycoprotein receptor.

The antiviral, anticellular, and immunomodulatory activities of interferon result from the internalized receptors that send signals to the appropriate cellular genes. Interferon inhibits cell growth in many cell types. Although there is marked cell-to-cell variation in sensitivity,[13] there is also a bimodal response in differentiation of cells, depending on the dose of interferon. With low-dose interferon, there may be an enhancement of differentiation, whereas there may be an inhibition of differentiation with high-dose interferon in various cell systems.[14]

The effects of interferons on the immune system are varied and are both cell-specific and interferon-specific. Interferons appear to inhibit the proliferation of cells, to enhance natural killer cell activity, and to enhance T-cell cytotoxicity and macrophage activation.[15-17] These considerations are important because minor depressions of the immune system appear to allow HPV either to become activated from latency or to remain clinically active. Patients with immunosuppressive diseases or those who receive exogenous corticosteroids may have activation of HPV disease. The use of interferon treatment in these patients is rarely successful.

The overall clinical response indicates that the two types of interferon treatment examined in this study have similar efficacy in the therapy of HPV disease. However, patients in the interferon alfa-2a group seemed to be a different population, disease had been present in these patients for a mean of 32.6 months before initiation of therapy, as compared with 14.2 months in patients treated with consensus interferon. It has been recognized that the longer the disease is clinically present, the less the likelihood for spontaneous remission. However, it is unknown whether disease present for 32.6 months is biologically different from disease present for 14.4 months.

Two patients in the interferon alfa-2a group had extensive grade 3 vulvar intraepithelial neoplasia in addition to extensive vulvar condyloma acuminatum. The administration of interferon alfa-2a caused a >50% decrease in the volume of condyloma but did not affect the grade 3 vulvar intraepithelial neoplasia. These two patients were subsequently treated with surgical removal of the neoplasia.

Patients in the interferon alfa-2a group received a mean of 88 MU per patient, as compared with 55.2 MU per patient in the consensus interferon group. The interferon alfa-2a protocol allowed for a continuation of the interferon alfa-2a in partial responders if it was thought to be clinically indicated. However, the results of this protocol suggest that the additional length of administration in the nonresponsive patient did not improve the overall clinical efficacy.

An important contribution of this study is to confirm

the value of adjunctive therapy in the treatment of HPV disease. Thirty of 34 patients eligible for additional adjunctive therapy chose to be treated; 20 of these 30 (67%) experienced complete clearing of condyloma. Therefore 41 of 55 patients (75%) included in this study were cleared of overt disease, whereas 8 patients were partial responders and 6 patients were lost to follow-up evaluation. The adjunctive therapy consisted of a variety of modalities; the largest number of patients received additional interferon therapy. It has been shown previously that physical ablation after interferon therapy increased clinical clearing; this suggests that further study is necessary.

The knowledge of the natural biologic characteristics of HPV infection is not well understood. The most effective therapy for the management of HPV is yet to be verified. However, data from this study support those of previous studies, which indicate that interferon may be used either as a primary treatment or as adjunctive therapy, either in conjunction with physical ablation or in combination with trichloroacetic acid or 5-fluorouracil. In addition, it is clear that any depression of cell-mediated immunity may allow growth of HPV or may make its control more difficult. Therefore patients with HPV disease must be instructed to stop smoking, since smoking causes mild immunodepression. More than 85% of the women with HPV disease in this study were smokers as compared with approximately 35% of women with HPV infection in the general population.

This study supports the concept that both interferons (consensus interferon and interferon alfa-2a) are effective in the therapy of overt condyloma acuminatum. Additional trials should be supported to determine the appropriate dosing for sequential therapy with laser ablation, cryotherapy, or trichloroacetic acid application. There is no evidence that the number of patients infected with HPV is decreasing, and newer approaches to management must be developed.

DRUG ABUSE IS CHILD ABUSE

Approximately 80% of the offspring of heroin-dependent women who receive no prenatal care experience serious medical problems such as intracranial hemorrhages and respiratory distress syndrome.

Neonates exposed to cocaine in utero have been documented to experience neurobehavioral abnormalities. They tend to be irritable and easily overstimulated.

The effects of cocaine abuse have been directly linked to certain congenital anomalies in infants, including intestinal atresia, limb reductions, and brain disruptions. These infants are also at a greater risk for congenital heart, urinary tract, and genitourinary defects.

The use of amphetamines during pregnancy may increase the occurrence of cardiovascular defects in the offspring.

If your patients are abusing drugs, tell them the facts, counsel them, recommend treatment programs...help them.

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

P<0.05 for cycles 1,2,3, and 5[1]

n = number of women with a bleeding event occurring during a cycle.

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions. 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Cross-sectional analysis of triplet birth weight

J. Stephen Jones, MD,[a] Roger B. Newman, MD,[a] and M. Clinton Miller, PhD[b]
Charleston, South Carolina

Parameters of fetal growth in triplet gestations are poorly studied and controversial. A cross-sectional analysis of triplet birth weight was performed to elucidate fetal growth patterns. Birth weight and gestational age data were analyzed on 580 infants in 196 triplet sets (eight stillborn infants excluded) between 1985 and 1988. Ovulation induction was used in approximately one half the gestations and early obstetric and ultrasonographic dating was available in all pregnancies. The mean triplet set and individual triplet weights versus gestational age were calculated with distinctly linear growth displayed between 22 to 38 weeks' gestation. Mean intratriplet differences at all gestational ages were determined. A comparison of singleton and triplet growth curves was constructed to show the distinct growth characteristics of triplets. (AM J OBSTET GYNECOL 1991;164:135-40.)

Key words: Triplets, fetal growth, intratriplet difference

Cross-sectional analysis of live-born birth weight data has historically been the basis for the establishment of intrauterine growth curves for singleton and twin pregnancies.[1-3] With the use of such growth curves it is possible to study factors that influence perinatal growth, and with the use of ultrasonography to follow intrauterine growth prospectively.

Although multiple gestations account for only 1% of all live-born births in the United States, they constitute 10% to 12% of perinatal deaths and 17% of intrauterine growth retardation.[4] Triplet gestations, as a subset of multiple gestations, occur spontaneously in approximately one in 10,000 live-born pregnancies.[5] Perinatal mortality rates ranging from 15% to 31% for triplet gestations have been reported.[6] In addition, the incidence of triplet birth is increasing because of the use of ovulation induction and in vitro fertilization.[7]

Data with regard to intrauterine growth parameters for triplets remain scarce. It is necessary to develop accurate growth curves for triplet gestations to aid our understanding of triplet growth, to assist in the diagnosis of intrauterine growth retardation, and it is hoped, to improve perinatal survival.

Methods

Anthropometric data from 196 triplet pregnancies delivered between 1985 and 1988 were analyzed. A description of the triplet pregnancies and details concerning their collection methods were previously published.[7] Data were collected with the assistance of ambulatory perinatal nurses employed by the Tokos Medical Corporation. The perinatal nurses were in daily contact with these women for the purpose of antepartum surveillance and preterm birth prevention. Individual patient management was at the discretion of a large number of attending obstetricians in both private and academic practices.

Data from 580 infants from these 196 triplet sets were analyzed; eight stillborn infants were excluded from the data set. Gestational dating was determined on the basis of the date of in vitro fertilization in 13 pregnancies and by the date of ovulation in 90 induced triplet gestations. In 93 spontaneous triplet gestations the estimated date of conception and gestational age were established on the basis of early obstetric and ultrasonographic criteria. Specific zygosity determinations were not available.

Birth weight (grams) was recorded for each live-born member of the triplet set as well as each triplet set. The gestational age and birth weight for individual triplets and triplet sets are reported as mean ± SD ($\bar{X} \pm SD$). Individual triplet birth weight descriptive statistics were performed independently of triplet sets because of the exclusion of the eight stillborn infants.

Growth curves were constructed by grouping infants according to gestational age. Gestational age at delivery was assigned by rounding to the nearest whole week (i.e., 32 3/7 weeks reported as 32 weeks, 32 4/7 weeks reported as 33 weeks). Statistical analysis of growth curves for both individual and triplet sets was performed with simple regression analysis. The first and second SDs were constructed by simple regression analysis with lines constructed from statistically derived SDs. The correlation coefficient was used to evaluate the accuracy of the presented growth curves.

Intratriplet difference was calculated as the differ-

*Mean ± SD.

ence between the largest and smallest triplet of each set. This difference is referred to as the maximum intratriplet difference. The percent maximum discordance was obtained by dividing the maximum intratriplet difference by the largest triplet of the set multiplied by 100. The individual triplet growth curve was compared with an established singleton curve.[2]

Results

The mean gestational age at delivery for this triplet series is 33.6 ± 3.1 weeks. The mean birth weight for each individual triplet is 1864 ± 543 gm and the mean birth weight for each triplet set is 5593 ± 1488 gm. Table I provides the number of triplets delivered at each gestational week along with the corresponding individual and triplet set birth weights (mean ± SD).

Fig. 1 shows the mean triplet set birth weight plotted against the gestational age at delivery. Triplet set growth is best described by the linear regression equation: W = −7737.1 + 402.56 (WG), where W = weight (grams) and WG = weeks' gestation at delivery. The correlation coefficient (R^2) between triplet set weight and gestational age is 0.956.

Fig. 2 shows the mean individual triplet birth weight plotted against the gestational age at delivery. A simple linear regression model best describes individual triplet growth (R^2 = 0.972) between gestational weeks 22 to 38. The equation for the line is as follows: W = −2311.3 + 124.73 (WG). On the basis of the linear growth model, individual triplets are predicted to gain approximately 125 gm per week during this linear phase of growth. Fig. 3 presents a depiction of the

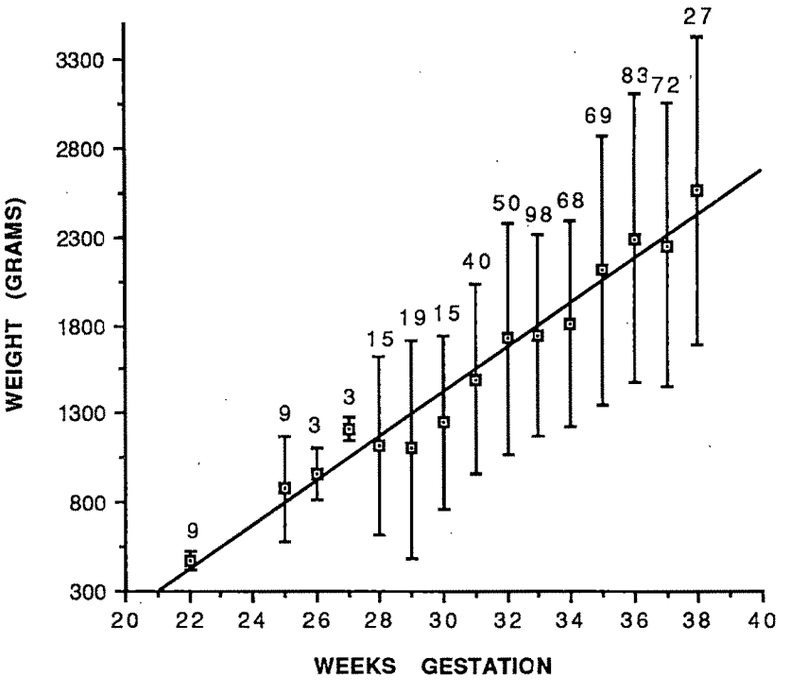

Fig. 2. Mean individual triplet birth weights (N = 580) in grams and 95% confidence limits by gestational age at delivery. Number of individual triplets delivered at each gestational week is listed above confidence bands. Regression line of best fit (R = 0.98) is superimposed on data.

individual triplet growth curve along with ± 1 and 2 smoothed SD linear regression lines.

For all the triplet sets the mean maximum discordance is 20.0%. Table II provides the mean maximum intratriplet weight difference at each gestational week (mean ± SD). Also presented is the calculated percent maximum discordance at each gestational week. Fig. 4 displays the histogram distribution of percent maximum discordance.

Approximately 80% of the triplet pregnancies were in white women. The triplet pregnancies in nonwhite women were nonuniformly distributed throughout all gestational ages, thus prohibiting statistical comparisons of racial differences.

Comment

The only previous cross-sectional analysis of triplet birth weight of a comparable size was reported by McKeown and Record[8] in 1952. In their article, 249 triplet gestations with 747 newborns beyond 28 weeks' gestation were analyzed. Gestational age was determined entirely on the basis of the onset of the last menstrual period. With the use of regression analysis it was determined that the mean fetal weight was similar for singleton and multiple gestations through the first two trimesters of pregnancy. At 27 weeks' gestation in triplets and at 30 weeks' gestation in twins, McKeown and Record found that the rate of growth appeared to decline progressively compared with singleton gestations.

Our data, collected between 1985 and 1988, represent a cross-sectional analysis of 196 triplet gestations with 580 live-born infants. Early gestational dating of these pregnancies on the basis of a known date of ovulation in over one half of these pregnancies and by contemporary obstetric and ultrasonographic criteria in the remainder ensure the accuracy of the cross-sectional analysis of our data.

Regression analysis of triplet growth for both individual and triplet sets reveals that the linear growth model best describes triplet growth between 22 and 38 weeks' gestation. Growth curves of higher order polynomial expressions could not improve on the linear model. The correlation coefficients of 0.956 for triplet sets and 0.972 for individual triplet growth are highly significant and indicate an excellent linear relationship.

Naeye et al.[3] supported McKeown and Record's observation that the intrauterine growth of twins did not parallel singleton growth. They concluded from live-born twin birth weight data that twin growth is similar to that of singletons until 30 weeks' gestation at which time twin growth "decreases" with respect to singletons throughout the remainder of pregnancy. With the use

of live-born birth weight data of twins Daw and Walker[9] also identified a "diminished rate of growth" for twins in the third trimester.

Our data on triplet growth when compared with previously reported singleton growth (Fig. 5) supports the concept that multiple and singleton gestations exhibit similar growth through 30 weeks. Beyond 30 weeks' gestation, the singleton fetus appears to accelerate in growth in a sigmoid manner. The triplet gestation lacks this acceleration in growth shown by singleton gestations. However, triplet growth remains linear throughout the third trimester rather than plateauing as previously suggested. The failure to identify an acceleration of growth in triplet pregnancies may be a result of suboptimal transfer of nutrients by the uteroplacental circulation in the third trimester as previously suggested for twin gestations.[10]

McKeown and Record previously speculated that individual growth in multiple gestations was not compromised until the total fetal weight exceeded 7 pounds (approximately 3200 gm). After 38 weeks in singleton pregnancies (corresponding to 3000 to 3200 gm), fetal growth begins to show a plateau effect. Triplets in our series continued to have linear growth well beyond a total intrauterine weight of 3200 gm that occurred at ≃ 28 weeks. The difference in growth also could be explained by contemporary antepartum management, including extensive bed rest and obstetric intervention for abnormal growth determined by ultrasonography.

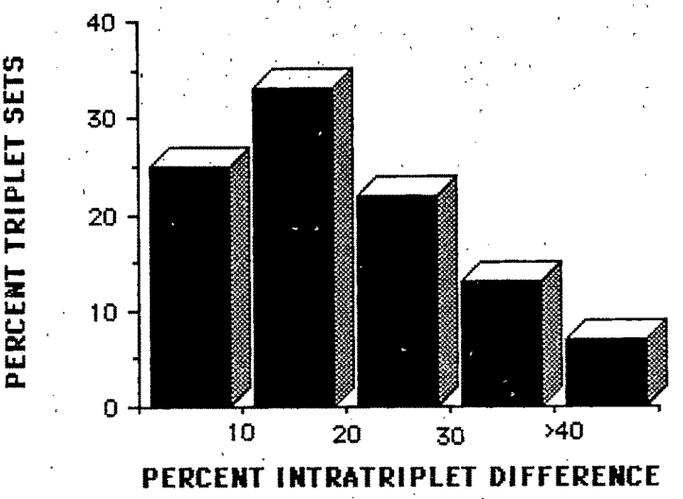

Fig. 4. Histogram of maximum triplet discordance. Vertical axis represents percentage of triplet sets displaying percentage of maximum triplet discordance, which is shown on *horizontal axis*. Maximum triplet discordance percentage defined as largest–smallest/largest × 100.

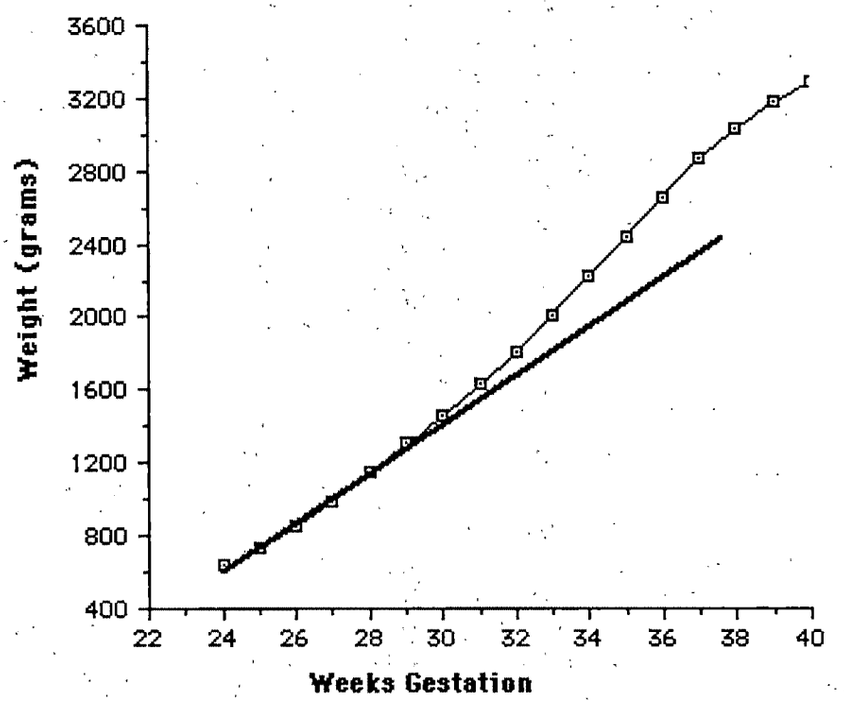

Fig. 5. Individual triplet growth curve *(solid black line)* compared with previously published singleton growth curve *(interrupted black line)*. The latter curve is from Brenner WE, Edelman DA, Hendricks CH. Am J Obstet Gynecol 1976;126:555-64.

Unfortunately, factors potentially affecting fetal weight gain including maternal smoking history, prenatal weight gain, and maternal stature were not available for statistical analysis.

Information derived from the analysis of intratriplet differences was very surprising. Discordance in twin growth is usually defined as a difference in a body weight exceeding 25%.[11] Mean intertwin weight differences at birth have been reported to be 10.3%.[12] Discordance can result from several factors including placental implantation differences, twin-to-twin transfusions, anomalies, and inherited genetic differences.

In this review 30.1% of the triplet gestations had an intratriplet discordance of at least 25% as determined

by the difference between the largest and smallest member of each triplet set. This compares with approximately 5% of twin pairs that display at least 25% discordance.[13] The histogram analysis of discordance suggests that approximately 7% of triplet sets displayed >40% discordance. We are unable to comment on the perinatal implications of such large degrees of discordance, but it appears that intratriplet growth differences are more pronounced than with twin gestations and the antepartum management implications may be different.

Singleton and twin growth curves have both been used to follow up triplet growth prospectively. Although ultrasonography is a useful instrument to predict fetal weight, the lack of accurate triplet growth curves limits our ability to interpret triplet growth. Regression analysis of mean triplet birth weight and gestational age allows the construction of a growth curve for triplets (Fig. 3).

Prospective ultrasonographic evaluation of twin gestations has been shown to be a sensitive method to detect abnormal growth and has resulted in a reduction of perinatal morbidity and mortality.[14] It is hoped that the establishment of a triplet growth curve with limits of variability defined by lines fitted to 1 and 2 SD lines at established weekly intervals will be helpful to prospectively follow triplet growth and reduce triplet morbidity and mortality.

The effects of indomethacin and a β-sympathomimetic agent on the fetal ductus arteriosus during treatment of premature labor: A randomized double-blind study

Marianne Eronen, MD,[a] Erkki Pesonen, MD,[a] Tapio Kurki, MD,[b] Olavi Ylikorkala, MD,[b] and Mikko Hallman, MD[b, c]

Helsinki, Finland

To study the effect of maternal indomethacin or nylidrine hydrochloride treatment on the fetal ductus arteriosus and the pulmonary artery, 27 women with threatened preterm labor between 24 and 34 weeks' gestation were studied by echocardiography. Fourteen women were treated with indomethacin and 13 with nylidrin. Both systolic and diastolic velocities in the ductus increased after administration of indomethacin indicating constriction in nine fetuses, and exceeded the corresponding velocities in the fetuses of the nylidrin group ($p = 0.001$). However, there were no changes in pulmonary artery flow velocities ($p > 0.5$). In the indomethacin group, there was a significant linear positive relationship between the gestational age and the change in ductal flow velocity. Three of the nine patients with ductal constriction also had tricuspid regurgitation. These findings indicate that indomethacin, not nylidrin, causes transient constriction of the ductus arteriosus and the constrictive response increases with the gestational age. We recommend echocardiographic surveillance of fetal hemodynamics when prostaglandin synthesis inhibitors are used in the treatment of spontaneous preterm labor. (AM J OBSTET GYNECOL 1991;164:141-6.)

Key words: Ductal blood flow velocity, human fetus, indomethacin, premature labor

Spontaneous premature delivery is the main cause of prematurity, accounting for a major part of serious neonatal morbidity and mortality.[1] Tocolytic therapy with β-sympathomimetic agents has been of minor or no significance in arresting preterm labor.[2] In addition, these agents have potentially harmful cardiovascular effects on both the mother[3] and fetus.[4] Because prostaglandins have an essential role in initiation and progression of labor,[5] the use of inhibitors of synthesis could be a logical approach to stop or delay preterm labor.[6, 7] These drugs may be a double-edged sword; besides inhibiting the production of uterine prostaglandins they also inhibit the production of fetal prostanoids, such as prostaglandin E_2 and prostacyclin, which are needed to keep the ductus open. In experimental animals, indomethacin and other cyclooxygenase inhibitors constrict the fetal ductus arteriosus,[8] increasing pulmonary vascular resistance and causing persistent fetal circulation with neonatal death.[9, 10] There are few case reports on pulmonary hypertension in the newborn[11-13] after the administration of indomethacin. Prospective trials with indomethacin have shown evidence of postponing premature labor,[11] and there has been little or no evidence of harmful effects in the neonates.[15-17] A recent study[18] presented evidence that indomethacin administration significantly increased the blood flow velocity in ductus arteriosus suggesting ductal constriction in seven of 14 fetuses studied. This suggests that maternal indomethacin causes ductal constriction in many fetuses.

In the present randomized study, we evaluated the ductal flow velocities and the hemodynamic signs of cardiac failure before, during, and after administration of either indomethacin or β-sympathomimetic tocolytic therapy during spontaneous premature labor. Our aim was to study whether ductal constriction, as defined by echocardiographic flow velocities, was specifically associated with indomethacin, and whether the degree of ductal constriction depends on the length of gestation.

Material and methods

Twenty-seven women with threatened premature birth were enrolled for the study in the University Central Hospital, Helsinki, between February 1988 and May 1989 (Table I). The inclusion criteria were as follows: uterine contractions at least 10-minute intervals for at least 2 hours between 24 and 34 weeks' gestation in singleton pregnancy; documented cervical changes (softening, opening); intact fetal membranes; absence

of intrauterine growth retardation, chorioamnionitis, placenta previa, maternal hypertension, sensitivity to salicylates, or history of peptic ulcer. None of the pregnant women received glucocorticoid treatment. The patients signed informed consent forms before participation in the study.

The patients were randomly allocated (a sealed envelope) to receive either indomethacin or nylidrin hydrochloride. The treatments were identical in appearance so that each patient received intravenous infusion (physiological saline solution) containing either nylidrin (13 patients; initial dose of 50 μg/min to maximal dose of 150 μg/min) or placebo, and rectal suppositories containing either placebo or 100 mg of indomethacin (14 patients); suppository treatment was continued with placebo capsules or capsules containing indomethacin 50 mg every 8 hours for a total of 72 hours.

The fetal heart was studied with two-dimensionally guided, pulsed, and continuous-wave Doppler equipment (Advanced Technology Laboratories 600 MK or Toshiba SSH 65 A Color Doppler system; 3.75 and 5 MHz) before the start of the therapy and 12 and 24 to 36 hours later. In addition, a scan was done 24 and 72 hours after discontinuation of therapy. Two-dimensional imaging was obtained from four approaches including four-chamber, long-axis, short-axis, and arch views. The ductal arch was obtained either in longitudinal or in short-axis view, depending on the orientation of the fetus. The aortic arch was identified in each case to avoid it being mistaken for the ductal arch. When measuring ductal velocities the sampling cursor was placed at the junction of the ductus and the descending aorta until the maximum velocity was attained.[19] Increase in the flow velocity indicates a narrowing of the vessel. In this study, ductal constriction was defined as the presence of a systolic velocity of >140 cm/sec in conjunction with a diastolic velocity of >35 cm/sec. Pulmonary artery flow velocities from the main pulmonary artery were recorded after withdrawal from the site of sampling from the ductus. The angle between the Doppler cursor and the direction of flow was always <15 degrees. Sample volume size was 0.1 to 0.3 cm. At least five waveforms were measured each time on the screen, and the mean of these values was recorded. The variation coefficient of velocities ranged between 11% and 23%.

Total cardiac dimension was measured by determining the distance between the anterior wall of the right ventricle and the posterior wall of the left ventricle at the level of both atrioventricular valves by four-chamber view.[20] The tricuspid valve regurgitation was visualized as a holosystolic regurgitant flow in the four-chamber view by pulsed, continuous-wave, and color Doppler ultrasonography. Fetal heart rate was registered. All studies were recorded on videotape for later playback and analysis.

The results are expressed as means ± SDs. The changes in the flow velocities were evaluated by the analysis of variance (repeated measurements) and the two-tailed, paired Student t test. To compare the velocities between the two tocolytic groups, an unpaired t test was used. The significance of the relationship between the ductal flow velocity and the gestational age was evaluated (Pearson's correlation coefficient). A p value of <0.05 was considered significant.

Results

There were no differences in clinical variables between the women who received indomethacin and those who received nylidrin (Table I). Indomethacin postponed the delivery on average by 7.6 weeks (SD, 5.8), nylidrin by 3.9 weeks (SD, 4.4) ($p = 0.07$). Of the 27 neonates, five required mechanical ventilation; two of them were in the indomethacin group. One infant (25 weeks' gestation; birth weight, 680 gm) died of streptococcus group B sepsis.

Recording of base-line echocardiograms failed in seven mothers because of maternal discomfort. Post-therapy blood flow measurements could not be obtained in six fetuses because of preterm delivery. The treatment was discontinued in one case because fetal echocardiography, performed after the first dose of indomethacin, revealed tetralogy of Fallot with the possibility of ductal-dependent pulmonary circulation.

In the indomethacin group the systolic velocities in the ductus arteriosus were higher than those in the nylidrin group (Table II). The difference in systolic velocities was evident at the 12-hour ($p = 0.003$) and the 24- to 36-hour ($p = 0.03$) echocardiogram. The systolic velocity exceeded 140 cm/sec in nine of the fetuses in the indomethacin group (Fig. 1). The diastolic flow velocities in the ductus were higher during indomethacin treatment than during nylidrin treatment ($p = 0.0008$); and the difference was significant at both the 12-hour ($p = 0.004$) and the 24- to 36-hour

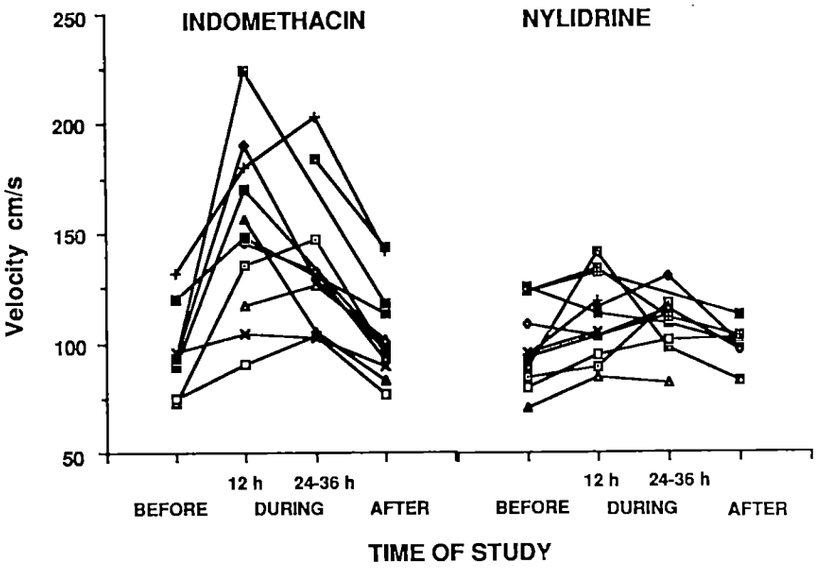

Fig. 1. Peak systolic velocities in fetal ductus before, during (at 12 hours and 24 to 36 hours), and after tocolytic therapy.

($p = 0.01$) echocardiogram. An increase in the diastolic velocity to >35 cm/sec was noticed in 10 of the fetuses in the indomethacin group (Fig. 2). Nine fetuses in the indomethacin group fulfilled the criteria of ductal constriction[19] when studied on average during 29.2 gestational weeks (range, 26.3 to 34 weeks). In the fetuses without ductal constriction, the mean gestational age was 25.5 weeks (range, 24.3 to 26.6 weeks; $p < 0.05$).

In the nylidrin group only one fetus (29 weeks' gestation) had a clearly elevated systolic velocity in the

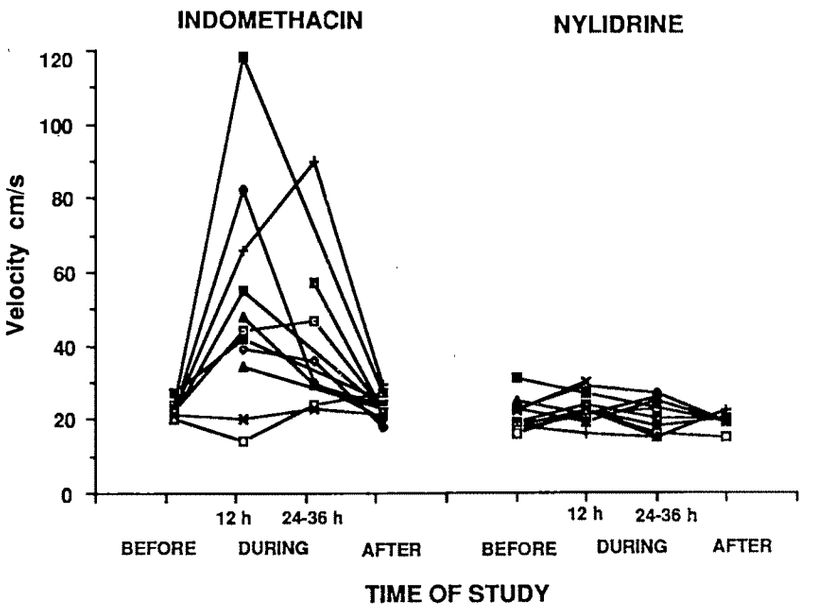

Fig. 2. Diastolic velocities in fetal ductus before, during (at 12 hours and 24 to 36 hours), and after tocolytic therapy.

ductus during treatment (baseline, 90 cm/sec to 142 cm/sec; fetal heart rate, 135 to 155 beats/min). None of these fetuses had a diastolic velocity of >35 cm/sec (range, 16 to 30 cm/sec). In this group three fetuses had atrial ectopic beats during therapy. The mean heart rate during nylidrin administration was significantly higher than during administration of indomethacin ($p = 0.002$).

A significant increase in ductal flow velocities occurred in both groups at the 12-hour echocardiogram. In the indomethacin group the change was significant in both systolic and diastolic velocities ($p = 0.006$ and $p = 0.01$; $n = 8$), whereas the nylidrin group only the systolic velocity increased ($p = 0.04$; $n = 11$). There were no statistically significant differences in the flow velocity values between the two measurements (at 12 and 24 to 36 hours) during the therapies with tocolytic agents.

There were no differences in pulmonary artery flow velocities between the groups ($p > 0.5$). The ratio of peak ductal/pulmonary artery flow was significantly higher in the indomethacin group than in the nylidrin group ($p = 0.0001$) (Table II).

Tricuspid valve regurgitation was detected in three fetuses. The mothers received indomethacin at 29, 32, and 34 weeks' gestation. Base-line echocardiograms were normal. The mean ductal systolic velocity in these fetuses was 204 cm/sec (range, 184 to 224 cm/sec) and mean diastolic velocity 86 cm/sec (range, 55 to 116 cm/sec). In one fetus (32 weeks' gestation) with the highest systolic (224 cm/sec) and diastolic (116 cm/sec) velocities, indomethacin was discontinued after two doses because of evidence of cardiac failure. The tricuspid regurgitation resolved within 24 hours after treatment in two fetuses and within 72 hours in one fetus (34 weeks' gestation).

The total cardiac dimensions increased by 8% ± 6% in fetuses with ductal constriction ($p = 0.02$). In fetuses with ductal constriction accompanied by tricuspid regurgitation, the cardiac dimensions increased by 19% ± 1%. Fetal echocardiograms 3 days after cessation of the treatment were normal in both groups (Figs. 1 and 2).

To evaluate whether the indomethacin-induced increase in ductal flow velocity was related to the length of gestation, the percentage increases in the ductal flow velocities were calculated. There was a significant positive relationship between the gestational age and the change in ductal systolic velocity ($r = 0.65$, $p = 0.01$, $n = 8$ Fig. 3). A less marked relationship was seen in diastolic velocity ($r = 0.42$, $p = 0.08$, $n = 8$, Fig. 3). There was no detectable relationship between the ductal flow velocities and the gestational age in the absence of indomethacin ($r = 0.004$, $p > 0.5$).

Comment

In the present randomized trial, it has been shown that indomethacin given during spontaneous preterm labor constricts the fetal ductus in nine of the 14 fetuses studied. The diagnosis was made on the basis of elevation of peak systolic and diastolic velocities after drug administration.[19] According to a study on fetal lambs

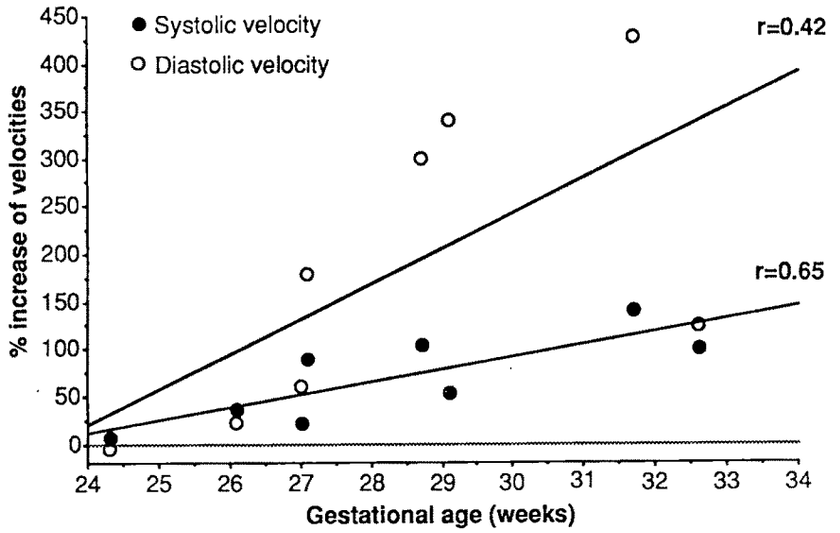

Fig. 3. Percentage increases of systolic and diastolic velocities in fetal ductus during maternal indomethacin treatment.

undergoing mechanical constriction of the ductus arteriosus, the square of peak systolic and diastolic velocities assessed by Doppler echocardiography correlated well with the pressure gradient across ductus arteriosus. Therefore increased ductal flow velocities reflect the constriction of the fetal ductus arteriosus. Our findings are supported by similar results from other groups.[18, 19]

Maternal indomethacin or nylidrin treatment did not affect the pulmonary artery flow velocities. This does not rule out the possibility of an indomethacin-induced increase in pulmonary vascular resistance[10] because a simultaneous increase in pulmonary arterial pressure may balance the pulmonary arterial flow velocity. However, according to the experimental study[10] an increase in pulmonary vascular resistance first took place after several days of surgical ligation of ductus arteriosus. In our study the reversibility of the ductal flow velocity after discontinuation of the drug suggests that the circulatory changes were reversible.

According to a recent study,[18] there was no correlation between the closure of the fetal ductus and the gestational age. In the present investigation the ductal constriction took place as early as 26 weeks' gestation and as late as 34 weeks' gestation. In addition, there was a significant linear positive relationship between the gestational age and the change in ductal flow velocity. The mean gestational age of the fetuses with ductal constriction was also higher than those without constriction. These findings may indicate that the ductus becomes more reactive to indomethacin with increasing gestational age.

Cardiac failure, as evidenced by cardiomegaly and tricuspid valve incompetence, is a severe complication of ductal constriction during fetal life. Elevated pressure in the right ventricular outflow tract may lead to endocardial ischemia with papillary muscle dysfunction.[9] In our study tricuspid regurgitation suggestive of heart failure developed in three of 14 fetuses in the indomethacin group. The ductal flow velocities (systolic mean, 203.7 cm/sec; diastolic mean, 86.3 cm/sec) were the highest recorded during the indomethacin treatment. In each case withdrawal of indomethacin abolished the tricuspid insufficiency within 72 hours. The range of the gestational ages of these fetuses—from 29 to 34 weeks—indicates that the risk of this serious complication is to be taken into consideration when prostaglandin inhibitors are used in premature labor and that indomethacin treatment might be safer in fetuses of <29 weeks' gestation.

Indomethacin-induced ductal constriction may impede either the pulmonary or systemic circulation in cases of cardiac anomalies with a ductus-dependent circulation. These malformations are, for example, tetralogy of Fallot, pulmonary atresia or stenosis, and coarctation or interruption of the aortic arch. One fetus in our study had tetralogy of Fallot. Indomethacin treatment was discontinued because of the risk of ductus-dependent pulmonary circulation. The female infant was born 1 day after administration of indomethacin at 34 weeks' gestation and had Apgar scores of 9. At 5 months of age a Blalock-Taussig shunt was performed because of hypoplastic pulmonary arteries.

In view of our study it is prudent to recommend careful evaluation of the risk/benefit ratio in the use of indomethacin during preterm labor. However, this drug seems to be more effective than ritodrine[11] or nylidrin in arresting preterm contractions, as evidenced

by the present data. In the present study the short course of indomethacin was not given when the mother was exposed to other drugs, which might potentiate ductal constriction (for example, glucocorticoids[21]), thus increasing the risk of cardiac failure. We recommend that ultrasonographic examination of the fetal heart be performed when indomethacin is used. Doppler ultrasonographic examination should include evaluation of the cardiac anatomy and atrioventricular valve function as well as the measurements of ductal flow velocities and the total cardiac dimension. Further studies are under way to identify the effect of indomethacin in the prevention of premature birth, the perinatal outcome, and the follow-up of these children.

A selective serotonin reuptake inhibitor, fluoxetine hydrochloride, modulates the pulsatile release of prolactin in postmenopausal women

Randall J. Urban, MD,[a, b] and Johannes D. Veldhuis, MD[b]
Galveston, Texas, and Charlottesville, Virginia

We investigated serotoninergic regulation of prolactin release in estrogen-withdrawn postmenopausal women by using a serotonin reuptake inhibitor. Subjects underwent frequent blood sampling after placebo (basal) or fluoxetine administration. Mean 24-hour serum prolactin concentrations increased significantly in response to fluoxetine. Objective pulse analysis revealed no change in prolactin pulse frequency with serotoninergic stimulation, but maximal serum prolactin peak heights increased significantly. Multiple-parameter deconvolution disclosed no change in prolactin half-life, but a significant increase in the total mass of prolactin secreted per 24 hours during fluoxetine administration. Cosinor analysis of the prolactin time series showed a significant increase in the circadian amplitude and mean without any change in the time of maximal concentration during treatment with fluoxetine. We conclude that short-term activation of the serotoninergic system in the absence of substantial estradiol and opiatergic tone significantly increases the secretion of prolactin in postmenopausal women. (AM J OBSTET GYNECOL 1991;164:147-52.)

Key words: Prolactin, serotonin, pulsatile release, fluoxetine

Under physiologic conditions, prolactin is secreted by the anterior pituitary gland in discrete pulses.[1, 2] The exact neuroendocrine mechanisms that control the frequency and amplitude of pulsatile prolactin release are not so well characterized as those that subserve other anterior pituitary hormones, such as the gonadotropins.[3]

The neurotransmitter chemical serotonin seems to participate in the regulation of prolactin secretion in man.[4] Early studies in human beings conflicted on whether pharmacologic probes that increased central nervous system serotonin levels stimulated prolactin release from the anterior pituitary gland.[5-7] Recently, studies in normal men and menstruating women showed that agents presumptively resulting in the elevation of central nervous system serotonin concentrations also increase mean serum prolactin concentrations.[8-10] Moreover, animal studies have shown that estradiol may play a stimulatory role in prolactin release in part by acting through endogenous opioid peptide pathways that activate release of serotonin.[11-15]

To assess the effects of putatively increased central nervous system serotonin levels in the absence of substantial estradiol and opiatergic tone, we studied the pulsatile secretory dynamics and clearance rates of prolactin in estrogen-deficient postmenopausal women basally and after treatment with a selective serotonin reuptake inhibitor, fluoxetine hydrochloride.[16, 17] Significant increases in serum prolactin concentrations with serotoninergic stimulation would indicate that direct or indirect stimulatory effects of serotonin can activate prolactin release in the absence of major influences of estradiol or the opiatergic pathway.

Methods

Patient characteristics. Seven healthy postmenopausal women (ages 53 to 61 years) with no acute or chronic illness, of normal body weight, and taking no medications participated in this study after provision of written informed consent that was approved by the Human Investigation Committee of the University of Virginia Health Sciences Center. Each subject had normal serum concentrations of thyroxine and prolactin, and normal results of biochemical tests of metabolic, hepatic, renal, and hematologic function. Any prior

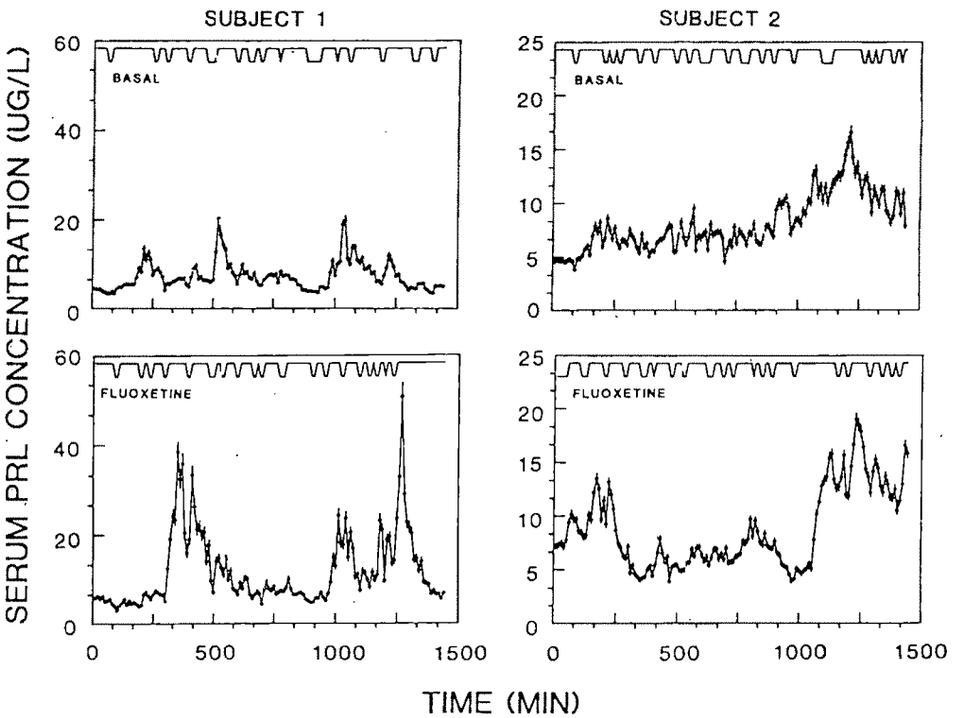

Fig. 1. Twenty-four–hour serum prolactin concentration profiles in two of seven estrogen-withdrawn postmenopausal women basally and during treatment with fluoxetine. Blood was sampled at 10-minute intervals for 24 hours and subsequent serum samples submitted to immunoradiometric assay to determine serial serum prolactin concentrations. *Vertical mark* through each data point denotes intrasample SD (see Methods). Schematized deflections at top of each panel identify significant prolactin pulses detected by Cluster analysis.[24] Zero time on X-axis is clock time of 8:00 AM. Patients were fed at 9:00 AM, 12:00 noon, and 6:00 PM. Lights out for sleeping was stipulated at 11:00 PM.

exogenous estrogens were withdrawn for at least 6 weeks. At the time of study, all women were demonstrably estrogen deficient (serum estradiol concentration <20 pg/ml) with elevated serum gonadotropin concentrations.

Clinical protocol. Volunteers were admitted to the University of Virginia Clinical Research Center on two separate occasions separated by 4 to 8 weeks in a prospective, double-blind, randomized placebo-controlled trial. The subjects received either fluoxetine or a nearly identical placebo pill before each study session. Thus some subjects received fluoxetine before their first admission and placebo before their second admission, whereas others received the treatments in reverse order. Each subject served as her own control and significant treatment differences were sought with the paired Student *t* test (see statistical analysis). Both investigator and subject were blinded to the drug identity. Fluoxetine was used in these preclinical studies under an investigator-initiated investigational new drug approved by the Food and Drug Administration. The drug was administered orally three times daily as 20 mg fluoxetine capsules for 6 days before study as well as during the 24 hours of blood sampling. Because the serum half-life of the drug is 1 to 3 days,[16] this paradigm assured that sampling was done at near steady-state drug levels. The dose of fluoxetine administered is equivalent to that recommended for treatment of depression.[16] The sampling protocol consisted of blood withdrawal (3 ml) every 10 minutes for 24 hours beginning at 8:00 AM from a venous catheter placed in a peripheral arm vein. Subjects were provided three regular meals and allowed to ambulate. An intravenous catheter was inserted at least 1 hour before serial sampling was initiated.

Prolactin assay. Serum samples were assayed in duplicate for prolactin content by a solid phase two-site immunoradiometric assay (Hybritech Inc., San Diego, Calif.). This method has a cross-reactivity of <0.01% with human luteinizing hormone, hu-

man follicle-stimulating hormone, human thyroid-stimulating hormone, human placental lactogen, and human chorionic gonadotropin. The lower limit of sensitivity of this assay is 3.0 μg/L and it has an intraassay coefficient of variation between 3.9% to 4.4% across the range of prolactin values encountered here.

Pulse analysis. An objective computer-based pulse detection method, Cluster analysis, was used to quantitate specific properties of pulsatile prolactin release.[18] To restrict false-negative and false-positive error rates to <10%, the following program parameters were used: (1) test Cluster sizes of two points for nadirs and one point for peaks; (2) pooled Student's *t* test statistics of 2.0 for significant increases and decreases; and (3) a power function model to estimate the individual dose-dependent within-sample variance from all 145 experimental samples in each subject.[1, 3, 18]

Multiple-parameter deconvolution. As described previously in detail,[19] a multiple-parameter deconvolution model was used to analyze the 24-hour serum prolactin concentration profiles basally and after treatment with fluoxetine. This model assumes that plasma hormone concentrations at any given instant are controlled by the combined effects of four secretion and clearance features: (1) locations; (2) amplitudes; and (3) durations of discrete secretory bursts acted on by (4) subject-specific endogenous metabolic clearance.[19] This model estimates the number, amplitude, and duration of all statistically significant underlying secretory events that give rise to the pulsatile plasma hormone concentration profile, and simultaneously calculates a subject-specific hormone half-life.

Cosinor analysis. Statistically based group cosinor analysis of circadian rhythmicity was carried out exactly as described earlier.[20] Briefly, we used simultaneous nonlinear, least squares curve fitting of all data sets and their dose-dependent intrasample variances to compute the group mesor (mean), amplitude, and acrophase (time of maximal concentrations) with conjoint asymmetric statistical confidence limits for the group of women.

Statistical analysis. For Gaussian-distributed measures (means), within-subject differences were sought by paired two-tailed Student's *t* test. Because of departures from normality shown by the Wilks-Shapiro statistic, individual pulse characteristics were compared after logarithmic transformation with subsequent paired two-tailed Student's *t* test.[3] Results are expressed as means ± SEM. Statistical significance was construed for $p \leq 0.05$.

Results

Mean serum prolactin concentrations. The 24-hour mean serum prolactin concentration was significantly increased during treatment with fluoxetine (basal, 9.6 ± 1.6 μg/L vs fluoxetine, 11.1 ± 1.7 μg/L, $p \leq 0.05$).

Table I. Characteristics of specific prolactin pulse properties before and during fluoxetine administration

Pulse characteristics	*Basal*	*Fluoxetine*
Prolactin pulse frequency (pulses/24 hr)	18 ± 1*	18 ± 1
Prolactin interpulse interval (min)	72 ± 8	70 ± 5
Prolactin maximal peak height (μg/L)	11 ± 1	14 ± 1†
Prolactin valley mean concentration	9 ± 1	11 ± 1†

*Mean ± SEM; $n = 7$.
†Statistically significant, $p \leq 0.05$.

Prolactin pulsatility. Fig. 1 shows two of the seven 24-hour prolactin time series basally and after treatment with fluoxetine. Table I summarizes individual values for prolactin pulse characteristics. With fluoxetine treatment, there was a significant increase in the maximal prolactin peak height and prolactin mean interpulse valley concentration. There was no change in prolactin pulse frequency or interpulse interval. Fig. 2 shows values for individual subject's significant prolactin pulse characteristics that were statistically significant (Table II).

Multiple-parameter deconvolution. Fig. 3 depicts the fit of the deconvolution model (calculated curves) and the computed prolactin secretory bursts basally and after treatment with fluoxetine in one woman. As summarized in Table II, there was a significant increase in the mass of prolactin secreted per 24 hours during fluoxetine treatment, but no significant changes in prolactin secretory burst half-duration (duration of the release episode at half-maximal amplitude), prolactin half-life, or interpeak basal secretion (data not shown). The intersecretory burst intervals calculated by the deconvolution method basally and during fluoxetine treatment (basal, 72 minutes ± 9 minutes vs fluoxetine, 64 minutes ± 7 minutes) were similar to those calculated by Cluster analysis (Table I).

Cosinor analysis. Measures of the prolactin circadian rhythmicity basally and after treatment with fluoxetine are summarized in Table III. There were significant increases in the amplitude of the circadian rhythm and the mean about which the rhythm oscillates (mesor) during fluoxetine treatment. There was no change in the time when the maximal value of the circadian rhythm occurred (acrophase).

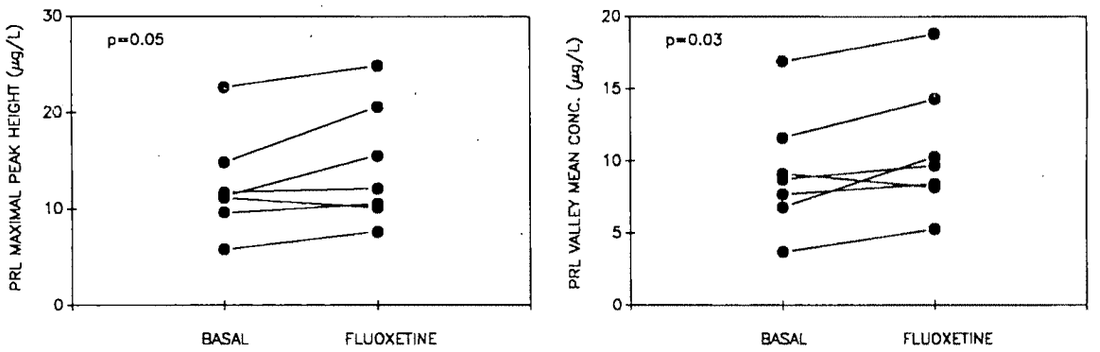

Fig. 2. Individual subject values for significant serum prolactin pulse characteristics, viz., maximal peak height *(left panel)*, and interpeak valley mean serum prolactin concentration *(right panel)* basally and during treatment with fluoxetine.

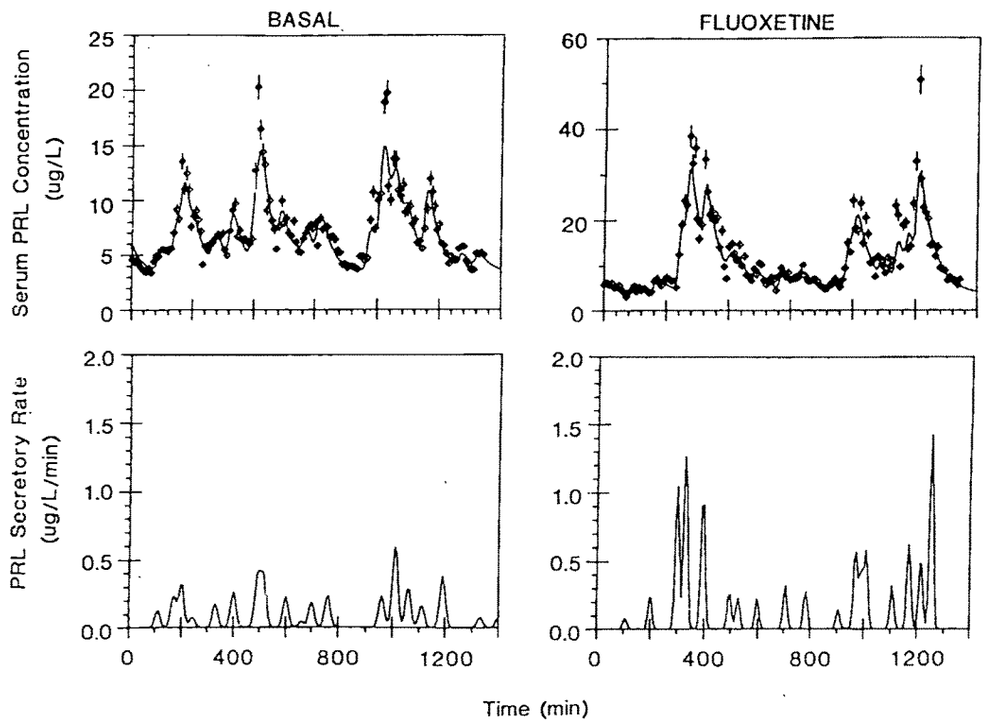

Fig. 3. Reconvolution fit (calculated curve through observed data) and computed prolactin secretory bursts basally and during treatment with fluoxetine in one subject. Fitted continuous curve gives deconvolution-calculated serum prolactin concentrations. Distinct bursts are secretory events computed to give rise to serum prolactin pulse profile.[19]

Comment

We investigated the effects of the selective serotonin reuptake inhibitor, fluoxetine, on the pulsatile secretion and metabolic clearance of prolactin in estrogen-deficient postmenopausal women. We found that presumptive stimulation of serotoninergic pathways increases serum prolactin concentrations in this clinical paradigm (decreased estradiol and low opiatergic tone), and does so by modulation of prolactin secretory burst amplitude without affecting prolactin pulse frequency or its circadian acrophase.

The increased mean serum prolactin concentrations observed after serotoninergic stimulation in this study are consistent with results reported for other agents

previously,[5-10] although the other agents were not so selective as fluoxetine in stimulation of serotoninergic receptors alone. The rise in serum prolactin concentrations was not so great as that in earlier studies. However, these previous studies were done in the presence of estradiol and opiatergic tone.

Opiates have been shown to stimulate prolactin release in adult rats through a serotoninergic mechanism, and in neonatal rats through a nonserotoninergic mechanism.[13, 14] Moreover, estradiol has been implicated in stimulation of prolactin release through an endogenous opioid peptide system.[11, 12] The importance of ovarian hormones in modifying serotoninergic regulation of prolactin release has been suggested further by studies that delineate differential effects of serotonin on prolactin secretion in the rat in proestrus and late pregnancy.[15]

In the present studies in estrogen-deficient postmenopausal women, we could examine the effects of serotoninergic stimulation in the absence of significant estrogenic and opiatergic tone.[17] Under these endocrinologically defined conditions, we observed selective amplitude modulation of prolactin secretion by serotonin without any significant alterations in prolactin pulse frequency, half-life, or circadian acrophase. The observed increase in the mass of prolactin secreted per burst could be a result of direct or indirect stimulatory effects of serotonin on prolactin secretion at the level of the hypothalamus or the pituitary gland. The present studies do not allow us to infer whether this mechanism also subserves the stimulatory actions of opiates and estrogen on prolactin secretion in man. However, if significant increases in serum prolactin concentrations occur in postmenopausal women who are estrogen-deficient while taking fluoxetine, then the prolactin response in women taking fluoxetine who are not estrogen-deficient (normally cycling women and postmenopausal women receiving estrogen replacement) may be even more pronounced. For example, hyperprolactinemia can raise undue clinical concerns with regard to a prolactinoma or other nondrug-related pathophysiology. Further studies are likely to help delineate the exact nature of putative interactions among estrogen, opiates, and serotonin that participate in the coordinate regulation of prolactin secretion in different clinical settings.

We conclude that serotoninergic stimulation can augment the secretion of prolactin in the absence of significant amounts of estradiol and opiatergic tone in postmenopausal persons.

We thank the Eli Lilly Company (Indianapolis, Ind.) for the generous donation of fluoxetine; Patsy Craig for her skillful assistance; Paula P. Azimi for the artwork; Sandra Jackson and the expert nursing staff at the University of Virginia Clinical Research Center for conduct of the research protocols; and Ginger Bauler and Catherine Kern of the Clinical Research Center Core Laboratory for immunoradiometric assay of prolactin.

Table II. Prolactin secretion and clearance calculations in one representative subject basally and during fluoxetine treatment

Parameters	*Basal*	*Fluoxetine*
Secretory burst half-duration (min)	25 ± 5*	18 ± 3
Prolactin half-life (min)	30 ± 5	38 ± 5
Prolactin daily secretory mass (μg/L/24 hr)	110 ± 15	170 ± 30†

*Mean ± SEM.
†Statistically significant, $p \leq 0.05$.

Table III. Twenty-four hour rhythms in serum prolactin concentrations in seven postmenopausal women studied basally and during treatment with fluoxetine

Parameters	*Basal*	*Fluoxetine*
Circadian amplitude (μg/L)	1.3 ± 0.3*	2.1 ± 0.3†
Time of maximal concentration (acrophase, min before 8:00 AM)	450 ± 20	500 ± 20
Group mean (mesor) (μg/L)	5.0 ± 0.2	6.3 ± 0.2†

*Mean ± SEM; $n = 7$.
†Statistically significant, $p \leq 0.05$.

Endoscopic sclerotherapy in extrahepatic portal hypertension in pregnancy

David Pauzner, MD,[a] Igal Wolman, MD,[a] David Niv, MD,[b] Amos Ber, MD,[a] and Menachem P. David, MD[a]

Tel-Aviv, Israel

Extrahepatic portal hypertension usually occurs during childhood, but a substantial number of patients may reach adult life. There is a general agreement that pregnancy may become hazardous to these patients, and some authors even consider this condition as a contraindication to conceiving. A case of endoscopic sclerotherapy in such a patient is herein presented, and the approach to such patients is discussed. (AM J OBSTET GYNECOL 1991;164:152-3.)

Key words: Extrahepatic portal hypertension, endoscopic sclerotherapy

Extrahepatic portal hypertension usually occurs during childhood or adolescence. The etiologic processes involve venous obstruction. Since liver function is usually preserved and the reproductive system is seldom affected, an obstetric team is bound to encounter such patients.

Many authors agree that pregnancy may be hazardous to these patients, as it increases the frequency of variceal bleeding which in some instances may be fatal. A debate exists as to the management of variceal bleeding, whether these patients should conceive, and the mode of delivery.

Here we report two consecutive deliveries of the same patient with extrahepatic portal hypertension, treated by endoscopic sclerotherapy.

Case report

A 23-year-old woman, para 0, gravida 1, was admitted to our ward because of hematemesis in her thirty-fifth week of pregnancy. Her history revealed portal

vein thrombosis verified by angiography at 15 years of age. A splenectomy was performed 2 years later because of variceal bleeding, and esophageal transection was done the following year because of recurrent episodes of variceal bleeding. During the 3 years before this admission she was treated successfully by sclerotherapy because of few bleeding episodes.

On admission blood pressure was 130/80 mm Hg and pulse rate was 76 beats/min. She was in good general condition with no signs of melena or further esophageal bleeding.

Endoscopic examination revealed two thrombotic varices in the lower esophagus, with no sign of ulceration or bleeding. The patient was treated with bed rest and antacids. Two weeks later, because of a sudden increase in blood pressure to 170/120 mm Hg, a low-segment cesarean section was performed, with delivery of a live male infant weighing 2500 gm with Apgar scores of 10 at 1 and 5 minutes. The postoperative period was uneventful.

Eighteen months after delivery, during which time one episode of hematemesis had occurred and was treated by sclerotherapy, she conceived again. An esophageal endoscopic evaluation performed during the first trimester of pregnancy revealed no dilated varices. Her pregnancy progressed uneventfully until the thirty-seventh week of gestation when a rise in blood pressure to 180/120 mm Hg was noted. The pregnancy was terminated by a low-segment cesarean section. She was delivered of a live female infant weighing 2550 gm with Apgar scores of 10 at 1 and 5 minutes. Her postoperative course was uneventful.

Comment

A debate exists in the literature as to the management of the parturient with extrahepatic portal hypertension and the best mode of delivery.

Kampelmakher[1] stated in 1957 that extrahepatic portal hypertension should be regarded as an absolute contraindication to pregnancy. Since than a major shift in opinions has occurred. At present most authors permit vaginal delivery in patients whose condition is stable but require a decompression operation in patients with bleeding before conception. Although theoretically the shunting procedure should be the most successful procedure, poor results are related to the poor condition of the veins available for anastomosis, the large number of collateral veins, and the size of the veins. One should remember that surgery should be indicated only as a last resort when all conservative measures have failed.

Recent years have witnessed a growing interest in endoscopic injection sclerosis. Several studies have confirmed that sclerotherapy controls acute variceal bleeding in 90% to 95% of patients and that it is more effective than balloon-tube tamponade or conservative treatment.[2]

Sclerotherapy usually eradicates the required number of varices and, when it is used repeatedly, a marked reduction in the number of subsequent bleeding episodes occurred.[3]

A full evaluation of the hemodynamic state and liver functions of such patients should be performed, and the presence of esophageal varices should be ruled out via an endoscope. If there are no other contraindications and the patient is generally in good health, she should be allowed to conceive, after having the risks involved explained to her.

If esophageal varices are shown, we suggest endoscopic injection sclerosis before conception and repeated endoscopic evaluation throughout pregnancy (at least once each trimester). Patients with uncontrolled bleeding in spite of endoscopic injection sclerosis should undergo a definitive shunt operation before conceiving.

The follow-up during pregnancy should be the same as for any other high-risk patient with the addition of absolute prohibition of aspirin ingestion and a vigorous treatment of any infection, as both seem to enhance esophageal bleeding.

The patient should be well sedated during the first stage of labor, preferably with an epidural anesthetic–morphine-bupivacaine combination. This method provides long-lasting pain relief with a stable cardiocirculatory state; thus the need for volume expansion before the sympathetic block is avoided.

The patient should not be allowed to strain, and the second stage of labor should be assisted by an instrumented delivery when feasible. Ten units of packed blood and a Blakemore tube should be prepared. Cesarean delivery should be performed for the usual obstetric indications.

Although conception and delivery impose a considerable risk on the patient with extrahepatic portal hypertension, we feel that they should not be contraindicated, although strict antenatal follow-up is mandatory.

Tables for estimation of individual risks of fetal neural tube and ventral wall defects, incorporating prior probability, maternal serum α-fetoprotein levels, and ultrasonographic examination results

James G. Thornton, MD, Richard J. Lilford, PhD, and Robert G. Newcombe, PhD
Leeds and Cardiff, United Kingdom

Tables are provided for estimation of the risk of open spina bifida in patients who have elevated maternal serum α-fetoprotein levels but normal results on detailed anatomy ultrasonographic scan. Risks are provided for various prior population risks, for various levels of elevated maternal serum α-fetoprotein, and for various assumptions about the sensitivity of ultrasonographic examination. The formula used is based on sequential multiplication of odds with the use of Bayes' theorem, but an arbitrary reduction (to the power of 0.5) in the degree to which ultrasonographic information modifies the odds has been made to allow for the nonindependence of ultrasonography and maternal serum α-fetoprotein tests. The wide range of resulting risks shows that the decision to offer amniocentesis after a negative scan should be individualized. (AM J OBSTET GYNECOL 1991;164:154-60.)

Key words: α-Fetoprotein, ultrasonography, neural tube defect, gastroschisis, exomphalos

Traditionally maternal serum α-fetoprotein (AFP) measurement has been used as a screening test for neural tube defects and ventral wall defects. The finding of maternal serum AFP above a certain cutoff level was an indication for the more specific diagnostic test of amniocentesis, providing no other obvious cause for the elevated maternal serum AFP value (e.g., multiple pregnancy, anencephaly, or wrong dates) was detected by low-level ultrasonographic scan. However, amniocentesis carries a 0.5% to 1% procedure-related abortion rate and the accuracy of ultrasonography has greatly improved with the introduction of high-resolution real-time scanning. This has led some authors[1] to rely exclusively on detailed ultrasonographic examination in patients with raised maternal serum AFP levels. It has also been argued[2] that maternal serum AFP screening could be omitted altogether and that detailed ultrasonographic examination is adequate for both screening and diagnosis. Nevertheless many authors[3,4] still recommend maternal serum AFP screening and this test is regaining popularity as a screening test for Down's syndrome and other trisomies.[5] Thus the issue of how to respond to a raised level warrants consideration. The decision to perform amniocentesis or rely exclusively on detailed scan depends on a trade-off between the greater accuracy of the former and the greater safety (in terms of iatrogenic fetal loss) of the latter. Whether the risk of amniocentesis is seen as worthwhile is a value decision that patients will make on the basis of the risks of amniocentesis versus the residual risk of a neural tube defect even if a detailed scan is normal. In this article we calculate the latter risks by statistical methods using reasonable assumptions based on literature review. Since anencephaly can be excluded with certainty by a detailed ultrasonographic scan once suspicion of a neural tube defect has been raised, we refer only to risks of lesser degrees of neural tube defect, namely, open spina bifida. In addition we do not dichotomize maternal serum AFP into "raised" or "normal" values but provide risks at a range of levels.

We have made use of tables for the risks of open spina bifida and abdominal wall defects at different levels of maternal serum AFP for populations with different incidences of open spina bifida.[6,7] These figures exclude cases of wrong gestational age, multiple pregnancy, and anencephaly, which is easily excluded by "low-level" scan. In this article we provide tables of the residual risk of open spina bifida for patients with various raised levels who have had a normal detailed ultrasonographic scan. The tables take into account the different underlying incidences of open spina bifida. Since false-positive results are rare on detailed scan and

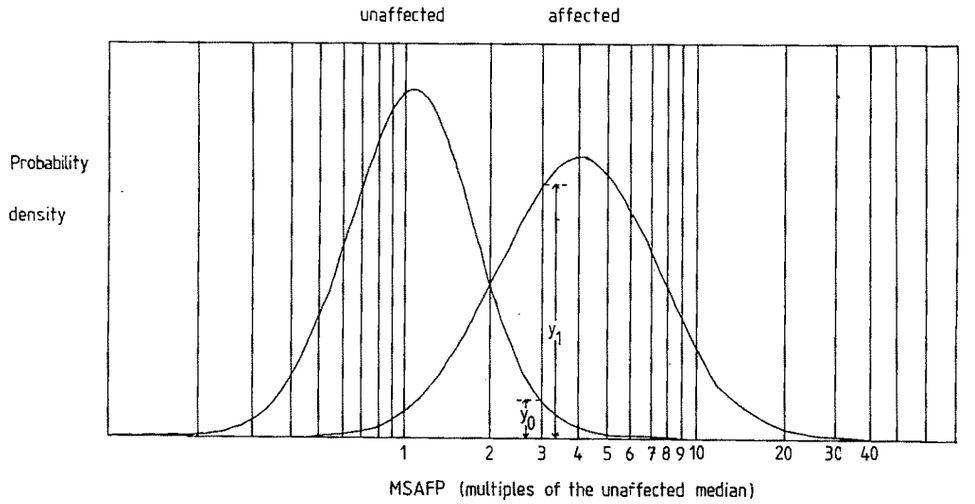

Fig. 1. Distribution of concentrations of maternal serum AFP in unaffected pregnancies and in pregnancies in which the fetus has open spina bifida. The *x* axis represents the gestational age–corrected concentration of maternal serum AFP plotted in multiples of the unaffected median. The y axis represents the probability density of values of multiples of the median with each population. Relative probability densities of affected (y_1) and unaffected pregnancies (y_0) at 3 multiples of the median are shown as an example.

since equivocal findings are likely to be excluded subsequently by amniocentesis, we have confined our attention to the predictive power of an apparently satisfactory normal ultrasonographic examination result. The tables are expanded to take into account different assumptions about the sensitivity of detailed ultrasonographic scan.

Methods

The risks of open spina bifida were calculated on the basis of the prior probability of open spina bifida (the population incidence before any diagnostic tests are performed), the level of maternal serum AFP (treated as a continuous variable), and the result of ultrasonographic examination. The population risk of ventral wall defect was taken to be a constant, 1 in 2000.[8] The recognized differences in population risk of open spina bifida were taken into account by giving posterior risks corresponding to various population risks ranging from 0.1 to 25 per 1000. Rates of open spina bifida in the United States have been published for different geographic areas and racial groups.[9] They range from 0.1 per 1000 for black women in the northwestern states to 1.0 per 1000 for white women in the southeast. The risks of open spina bifida and ventral wall defects in terms of maternal AFP levels were taken from Adams et al.[6] and expressed as likelihood ratios or relative risks.

The formula for calculating posterior odds, given a population incidence (prior odds) and the level of maternal serum AFP, is based on Bayes' theorem. The posterior odds against open spina bifida are calculated by multiplying the prior odds by the likelihood ratio.

	Affected	*Unaffected*
Prior odds	r	$1 - r$
AFP likelihood ratio	y_1	y_0
Posterior odds	ry_1	$y_0(1 - r)$

Posterior odds = Prior odds × Likelihood ratio

$$\frac{\text{Unaffected}}{\text{Affected}} = \frac{(1 - r)}{r} \times \frac{y_0}{y_1}$$

where r is the prior probability of neural tube defect (usually the population incidence) and Y_0 and y_1 denote ordinates or probability densities at the observed log maternal serum AFP values derived from distributions in unaffected and affected samples (Fig. 1).

This process is readily extended to take into account the value of a negative anatomic ultrasonographic result. The posterior odds become $\lambda\, y_0\, (1 - r)$ to $y_1 r$, where λ represents the negative diagnostic value of the scan (i.e., the likelihood ratio of a negative scan).

Assuming the scan had a false-negative rate, β, and a false-positive rate, α, we would have a likelihood ratio of $\lambda = (1 - \alpha)/\beta$. The error rates, α and β, will depend on the technical skill exercised and the level of tolerance of the ultrasonographer for suboptimal views of the spine. The λ value depends more dramatically on β than on α. Let us assume (somewhat arbitrarily and conservatively) that $\alpha = 0.05$. For values of β we consider three plausible false-negative rates: $\beta = 0.2$, 0.1, and 0.05. These would give λ values of 0.95/0.2 (4.75), 0.95/0.1 (9.5), and 0.95/0.05 (19), respectively.

Table I. Parameters of distributions of concentrations of maternal serum AFP in specimens with dates assigned by ultrasonography

	Geometric mean (multiples of median)	*Log_{10} multiples of median (mean ± SD)*
16-18 wk		
Unaffected	1.02	0.0065 ± 0.2050
Open spina bifida	5.42	0.7344 ± 0.2607
Ventral wall defect	8.65	0.9369 ± 0.6610
19-21 wk		
Unaffected	1.02	0.0065 ± 0.1710
Open spina bifida	3.17	0.5005 ± 0.2521
Ventral wall defect	8.65	0.9369 ± 0.6610

However, this simple multiplicative model, known as "independence Bayes'," is inappropriate here since it assumes that the information given by the ultrasonographic scan is of entirely independent discriminatory power to that provided by the maternal serum AFP value. This is unlikely to be the case since larger lesions are more likely to show up with either method. Independence Bayes' will therefore assign excessively polarized risks. We get around this by using a likelihood ratio less extreme than $(1 - \alpha)/\beta$ to modify the prior odds $y_0 (1 - r) : y_1 r$ into the posterior odds. Exactly how this should be done could be definitely established only by a very large study examining the relationship of maternal serum AFP and ultrasonography jointly to the true state of the fetus. This would be beyond our scope and likely also beyond that of others. A single-center study would need many years to accrue sufficient data, and technical improvements in ultrasonography would probably supersede the results before they were available. In a multicenter study it would be difficult to allow for heterogeneity in effective α and β rates between centers. In the absence of hard data, we try to devise a means of lengthening the odds but to a lesser degree than an independence Bayes' model.

We use

$$\frac{1 - r}{r} \times \frac{y_0}{y_1} \times \left(\frac{1 - \alpha}{\beta}\right)^{\gamma}$$

as our posterior odds, for some power γ between 0 (ignoring ultrasonography and assuming it gives identical information to maternal serum AFP) and 1 (assuming complete independence). The γ value depends on the degree of nonindependence; in the absence of directly pertinent data, we arbitrarily choose a location parameter of one half for our distribution of degrees of belief regarding γ. When this is done, the λ values corresponding to $\beta = 0.2$, 0.1, and 0.05 are reduced to 2.179, 3.082, and 4.359, respectively. It must be emphasized that the assumption that γ is one half as a measure of the degree of nonindependence of maternal serum AFP and ultrasonographic examination is arbitrary. Because many readers may be unhappy at this choice of γ, we also provide risk figures for cases in which ultrasonography provides no new information and where ultrasonography is completely independent of maternal serum AFP.

Quoted rates for sensitivity of ultrasonography for diagnosis of neural tube defect defect (assuming anencephaly has been excluded) range from 60% to 96%.[3, 10-12] The higher figure refers to centers of excellence but may be achievable in average examination units if the ultrasonographer has been alerted to the possibility of neural tube defects by the maternal serum AFP level. We therefore provide three risks assuming ultrasonographic sensitivity rates of 80%, 90%, and 95%. These correspond to false-negative rates, β, of 0.2, 0.1, and 0.05, respectively. There are no widely quoted rates for the specificity of ultrasonographic scan since for large, obvious lesions the false-positive rate will approach 0 and for doubtful lesions confirmation will usually be sought by amniocentesis before termination of pregnancy. We have therefore assumed a false-positive rate for ultrasonography of 5%, which is probably an overestimate but makes allowance for those cases where a satisfactory scan is impossible because of technical difficulties such as maternal obesity and posterior fetal position. Any overestimate will tend to reduce the likelihood ratio, λ, by which we modify the prior odds but the effect is very small.

The data relating maternal serum AFP to open spina bifida used in calculating posterior risks come from an updated version of the data Adams et al.[6] prepared as an unpublished supplement in February 1984, in which confirmation of dates and exclusion of multiple pregnancy and anencephaly by low-level ultrasonography are assumed already to have taken place. The parameters of the distributions of concentrations of maternal serum AFP are shown in Table I. The distributions of concentrations of maternal serum AFP for normal pregnancies and pregnancies affected by neural tube defects come from data reported by Wald et al.[13] for pregnancies where the gestational age was corrected for ultrasonographic results. Such data are not available for ventral wall defect–affected pregnancies, and therefore the parameters have been calculated from last menstrual period data by assuming that the distribution is shifted upward by 2%, the percentage of the shift found in unaffected pregnancies. In Tables II to IV, the risks of open spina bifida and ventral wall defect are reported for three assumptions about ultrasonography, namely, normal detailed anatomic scans of 80%, 90%, and 95% sensitivity, respectively.

Table II. Risks (1 in *n*) of open spina bifida and ventral wall defect by population incidence and maternal serum AFP at 16 to 18 weeks' gestation in patients who have had normal ultrasonographic examination of 80% sensitivity

The left-hand column gives risks of ventral wall defect and the other columns give risks of open spina bifida for various prior population incidences. At each level of maternal serum AFP and prior probability of open spina bifida three figures are given. The upper figure assumes that ultrasonography provides no information beyond maternal serum AFP ($\gamma = 0$), the lower figure assumes ultrasonography is completely independent of maternal serum AFP ($\gamma = 1$), and the middle figure in boldface type assumes $\gamma = 0.5$ and is our best estimate of any individual woman's true risk.

Results

Tables II to IV give risks (expressed as 1 in *n* to two significant digits) for ventral wall defect in the left-hand column and for open spina bifida in the other columns for various levels of maternal serum AFP tested at 16 to 18 weeks and for various population incidences of open spina bifida. At each level of maternal serum AFP and prior probability of open spina bifida three figures are given. The top figure assumes that ultrasonography provides no information beyond maternal serum AFP ($\gamma = 0$), the bottom figure assumes ultrasonography is completely independent of maternal serum AFP ($\gamma = 1$), and the middle figure (in boldface type) assumes $\gamma = 0.5$ and is our best estimate of any individual woman's true risk. In Tables II to IV the risks incorporating ultrasonographic information take into account a normal detailed anatomic ultrasonogram of 80%, 90%, and 95% sensitivity, respectively.

The risks for ventral wall defect in the first column of each table assume a constant population incidence of 0.5 per 1000 (Adams et al. Unpublished results, 1984).

Illustrative cases

Case 1. A woman from South Wales, who had a previous affected child, had a maternal serum AFP value of 2.5 multiples of the median at 16 weeks and a normal ultrasonographic scan performed by an experienced ultrasonographer with knowledge of her history and maternal serum AFP level. In this population (previous affected child in a high-incidence area) the prior probability of open spina bifida before any investigations is about 1 in 40 (25/1000) after anencephaly is excluded. Assuming a negative ultrasonographic examination of 95% sensitivity, the risk of open spina bifida is estimated at 1 in 81 (Table IV); therefore the patient decided to undergo amniocentesis.

Case 2. A woman from southeast England, with a previous normal delivery, had a maternal serum AFP level of 5 multiples of the median at 17 weeks and a normal ultrasonographic scan performed in a district hospital by an ultrasonographer trained to detect the banana and lemon signs. This patient's prior probability of open spina bifida, excluding anencephaly, is approximately 1 in 1000.[8] Assuming the ultrasonographic scan is 80% sensitive, her posterior probability after scan and with a very high maternal serum AFP level is estimated at 1 in 10 (Table II). She elected to undergo amniocentesis.

Case 3. A woman from South Wales had a maternal serum AFP value of 2.5 multiples of the median in her

Table III. Risks (1 in *n*) of open spina bifida and ventral wall defect by population incidence and maternal serum AFP in patients who have had normal ultrasonographic examination of 90% sensitivity

first pregnancy at 17 weeks and a normal detailed ultrasonographic scan, by an experienced radiologist who believes that this sensitivity is 90% when he is alerted to a raised maternal serum AFP value. Her prior probability of open spina bifida was 2 in 1000,[12] and after maternal serum AFP and ultrasonographic scanning the posterior probability of spina bifida is 1 in 730 (Table III) and that of ventral wall defect is 1 in 4500. She elected not to undergo amniocentesis. Note that had the detailed ultrasonographic scan not been performed, she would have been assigned a risk of open spina bifida of 1 in 240 (Table III, upper risk figure) and might well have opted for amniocentesis.

Comment

The major criticism of our calculation is likely to be the assumption of a value of 0.5 for the power γ, by which we reduce the modifying predictive power of a negative ultrasonographic scan to allow for its nonindependence from the maternal serum AFP level. Our defense is that, if the undoubtedly pertinent data that a negative ultrasonographic examination provides are to be used at all in risk revision, then some arbitrary assumption must be made. The necessarily enormous trial in which ultrasonography and maternal serum AFP screening are combined is probably impossible to complete before its findings would be superseded by technical advances in ultrasonography techniques. It may be argued that our value for γ of 0.5 is too low because the two tests, maternal serum AFP and ultrasonography, are closely dependent, with both detecting the larger lesions. We believe that this is unlikely. Although both tests are likely to detect larger lesions, there are other factors besides small size that cause false-negative results and are not linked. False-negative maternal serum AFP results may be caused by laboratory and clerical errors and by skin covering lesions that are usually but not necessarily small. False-negative ultrasonographic results may be caused by operator lapses, faulty identification of anatomy, maternal obesity, or fetal position, none of which is necessarily related to small lesions. In view of this we believe our choice of a value of 0.5 for γ is conservative and, if anything, is likely to underestimate the diagnostic value of a negative ultrasonographic scan. One way of testing the degree of dependence of ultrasonographic examination and maternal serum AFP would be to obtain data on the sizes of lesions detected and missed by both methods. We do not have access to such a data base, but if such information could be obtained elsewhere, a somewhat more objective value for γ could be chosen. Because of our uncertainty about the correct value for γ, we have taken care to present the risks bounded by the range if γ were 0 and if γ were 1. Any individual woman's risk must be within this range, and we believe the figures in boldface type in our tables are reasonable estimates.

Our estimates of 80%, 90%, and 95% sensitivity for ultrasonography may be questioned by some. We believe that these figures are justified for a level II scan

For explanation of values see footnote to Table II.

performed in a well-ordered unit where the ultrasonographer has been alerted to the possibility of open spina bifida by the raised maternal serum AFP level. The middle and lower rows of risks in our tables are *not* applicable if only a low-level dating and fetal counting scan has been performed. Such an examination will probably exclude anencephaly but is unlikely to achieve even 80% sensitivity for open spina bifida. The upper rows of figures in each table would be suitable in this situation if no higher-level scan was possible.

In our analysis of the risk of ventral wall defects we have assumed that ultrasonography has the same sensitivity and specificity as it does in the detection of open spina bifida. Some readers may feel sensitivities of 80% and 90% are underestimates for ventral wall defects and claim that virtually all cases of exomphalos (that is, >98%) will be detected by scan. Although a small gastroschisis is more easily missed, it has a good prognosis and is seldom an indication for prenatal intervention. Such readers may wish to ignore the tables dealing with ventral wall defects and concentrate on the possibility of missing the more common, more serious, and more difficult to detect open spina bifida.

The wide variation in risks of open spina bifida at various maternal serum AFP levels and prior odds indicate that a blanket policy neither of always proceeding to amniocentesis after a raised maternal serum AFP value, whatever the ultrasonographic findings, nor of omitting amniocentesis whenever ultrasonographic examination results are normal, can be justified. The risk assessment and consequent decision must be individualized on the basis of the patient's values and the probabilities. These tables provide a rational and convenient basis for estimation of the probabilities. In particular, because most of the additional cases of neural tube defect detected by amniotic fluid AFP testing will be relatively small and because this is the group from which most severely handicapped long-term survivors come, it is important that a policy of always omitting amniocentesis if the ultrasonographic examination result is normal is not followed. The opposite policy of always performing amniocentesis above an arbitrary maternal serum AFP cutoff of, for example, 2.5 multiples of the median, whatever the ultrasonographic findings and population incidence, is likely to result in high acceptance rates since most patients will have been led to believe that the abnormal maternal serum AFP value put them in a high-risk category. Nevertheless, it will often result in amniocenteses at extremely low fetal risks. These will sometimes be below the original population incidence, occasionally an order of magnitude below the amniocentesis procedure–related abortion rate, and often below the risk that an appropriately informed patient would regard as sufficient to warrant an invasive test.

The calculations given here indicate the considerably lower risks that may be assigned to pregnancies for which a demonstrably normal result has been obtained by ultrasonography. The posterior risk is not 0, because false-negative results do occur, but can be considerably

better than the values given in the tables of Adams et al. We do not consider explicitly here what to do if the scan shows abnormality suggestive but not diagnostic of open spina bifida (e.g., the "lemon" and "banana" frontal and cerebellar signs[14, 15] with no obvious spinal defect); in this case amniocentesis presumably would be recommended anyway, practically irrespective of the maternal serum AFP level.

Appendix

For users who prefer to calculate individual risks by computer rather than with tables we provide this formula, which can be easily programmed into a portable microcomputer.

y_i = Probability distribution of unaffected ($i = 1$), open spina bifida ($i = 2$), and ventral wall defect ($i = 3$) pregnancies at appropriate AFP multiples of the median

x = Log_{10} multiples of the median

n_i = Prior probability 1 in n of open spina bifida ($i = 2$) or ventral wall defect ($i = 3$)

se = Sensitivity % assumed for ultrasound

sp = Specificity % assumed for ultrasound

γ = 0, 0.5, or 1 (adjustment factor for nonindependence of tests)

r_i = Posterior odds for open spina bifida ($i = 2$) or ventral wall defect ($i = 3$)

μ_i = Mean $\log_{10}$ AFP multiples of the median at appropriate gestation from Table I

σ_i = SD $\log_{10}$ AFP multiples of the median at appropriate gestation from Table I

$$y_i = \left(\frac{1}{\sigma_i}\right)^e - \frac{1}{2}\left(\frac{x - \mu_i}{\sigma_i}\right)^2$$

$$r_i = (n - 1)\left(\frac{y_t}{y_i}\right)\left(\frac{sp}{100 - se}\right)^\gamma$$

If risks are preferred to odds:

Risk of open spina bifida or ventral wall defect = 1 in $r_t + 1$

Risk of open spina bifida and/or ventral wall defect = 1 in $1/(1 - r_2r_3/(1 + r_2)(1 + r_3))$

Heterotopic pregnancies after in vitro fertilization and embryo transfer

Botros Rizk, MD, Seang Lin Tan, MD, Samuel Morcos, MD, Andrew Riddle, MD, Peter Brinsden, MD, Bridgett A. Mason, MB, BS, and Robert G. Edwards, PhD, DSc
London, England

Seventeen cases of heterotopic pregnancies are reported among 1648 clinical pregnancies after in vitro fertilization. The high prevalence of tubal damage among IVF patients and the use of superovulation and multiple embryo transfer might predispose patients to the condition. Nine patients reported abdominal pain and vaginal bleeding, five patients did not have symptoms, and three had acute abdominal emergencies. Transvaginal ultrasonography was superior to transabdominal ultrasonography in the diagnosis of extrauterine pregnancies. The presence of an intrauterine gestation sac in a patient without symptoms should not exclude the diagnosis of a concomitant extrauterine pregnancy until the pelvis is carefully visualized. Early diagnoses of viable ectopic pregnancies before rupture abolishes mortality and morbidity and offers the chance of patient selection for conservative treatment. In two patients the extrauterine gestation sac was treated by transvaginal aspiration and injection of potassium chloride under ultrasonographic guidance. The outcome of the intrauterine pregnancy was favorable regardless of the method of treatment of the ectopic pregnancy. (AM J OBSTET GYNECOL 1991;164:161-4.)

Key words: Heterotopic pregnancy, in vitro fertilization, embryo transfer

The incidence of combined intrauterine and extrauterine pregnancy is evidently higher after in vitro fertilization (IVF) than in spontaneous pregnancies. Our data indicate a frequency of 1% in clinical pregnancies after IVF as compared with 1 in 3889 and 1 in 6778 after spontaneous conceptions.[1,2] Diagnosis of heterotopic pregnancy is difficult because symptoms of ectopic gestation may be attributed to complications of intrauterine pregnancy, and a patient without symptoms may not raise suspicions of ectopic gestation. Transvaginal ultrasonography helps in the diagnosis and should be used in suspected cases, but assays of β-human chorionic gonadotropin (β-hCG), which are usually low in ectopic pregnancies, can be unhelpful inasmuch as they might indicate normal ranges in combined pregnancies.

Management of combined pregnancies presents another difficulty. Laparotomy during the first trimester might threaten the intrauterine pregnancy and ultrasonography-guided aspiration procedures have limitations, although they are valuable in properly selected cases. In the present study we discuss the factors responsible for the increased frequency of combined pregnancy after IVF, the variations in clinical presentation, and the value of transvaginal ultrasonography in early diagnosis and therapy.

Material and methods

Seventeen cases of combined intrauterine and extrauterine pregnancies were encountered among 1648 clinical pregnancies after IVF at the Bourn Hallam Medical Centre between 1985 and 1989. The methods of ovarian stimulation, ultrasonographic and endocrine monitoring, oocyte retrieval, fertilization of oocytes, and growth of embryos in vitro used in this period have been described previously.[3] Embryo replacements were mostly carried out 2½ days after oocyte retrieval with a catheter (Wallace, Colchester, United Kingdom), and anesthetic agents were not administered to any of the 17 patients. A maximum of four embryos were replaced in 0.02 ml of culture medium deposited near the fundus.

Urinary and serum β-hCG levels were measured 15 days after oocyte recovery. Serial β-hCG levels were measured at 5 days' interval. At Bourn Hall Clinic, transabdominal followed by transvaginal ultrasonography was performed 35 days after oocyte recovery; at Hallam Medical Centre, only transabdominal ultrasonography was performed. Patients returned to the referring obstetricians during the pregnancy and delivery.

Results

Patients and stimulation. The mean age of the 17 patients was 30.5 years (range, 20 to 37 years). Fifteen of them had tubal damage, one had endometriosis with patent tubes, and one had not conceived after repeated donor insemination. Five patients had previous tubal surgery and two had previous ectopic pregnancies.

Ovarian stimulation was achieved by the use of clomiphene citrate (Serophene, Serono Laboratories, Welwyn Garden City, United Kingdom) and human menopausal gonadotropin (hMG; Pergonal, Serono) in 10 patients. Purified follicle-stimulating hormone (FSH; Metrodin, Serono) was added to this regime in two patients. The gonadotropin-releasing hormone (GnRH) agonist (Suprefact, Hoechst, Hounslow, United Kingdom), and hMG were used for stimulation in five patients. The number of oocytes retrieved varied between three and 16, and four embryos were replaced in eight patients, three in seven patients, and two in two patients.

Symptoms and diagnoses. The symptoms at first examination in the 17 patients were quite variable, with abdominal pain and vaginal bleeding in nine patients, acute surgical abdominal emergencies in three, and no symptoms in the remaining five patients (Table I). Fifteen patients had ultrasonographic scans before the definitive management of the extrauterine pregnancy began and the ectopic pregnancy ruptured before ultrasonography in two patients. In 10 patients who had abdominal scans, a correct diagnosis was made in only five and was strongly suspected in one (50%). Each of the five patients who had abdominal and transvaginal scans had a correct diagnosis. Overall there was a 66.6% diagnostic accuracy rate. The earliest diagnosis of an extrauterine gestation sac was made at 6 weeks' gestation. Levels of plasma β-hCG 15 days after oocyte recovery ranged from 141 to 2710 IU/L, and serial assays over 20 days were frequently within the normal range for normal intrauterine pregnancies.

Outcome of pregnancies. The extrauterine gestation sac ruptured spontaneously in eight patients. Surgical excision was performed in 14 patients. Unilateral salpingectomy was performed in 10 patients, bilateral salpingectomy in two patients, and salpingo-oophorectomy in two patients. A local injection of potassium chloride in the fetal heart followed by aspiration of the gestation sac was performed in two patients under transvaginal ultrasonographic control. One extrauterine gestation sac resolved spontaneously.

At the time of the initial diagnosis, the viable intrauterine pregnancy was present in seven patients and twin intrauterine sacs were present in three others. One patient miscarried and the others progressed uneventfully with seven singleton deliveries, one twin, and one on-going pregnancy.

Case reports and series of heterotopic pregnancy after IVG–embryo transfer are presented in Table II.

Comment

There is a high incidence of combined heterotopic pregnancy after IVF, reaching 1% of all clinical pregnancies in our clinics between 1985 and 1989. Another recent series reported nine cases among 312 clinical IVF pregnancies (2.9%)[4] and a multicenter study that incorporated large IVF centers in the United Kingdom had 30 cases among 2234 clinical pregnancies (1.3%).[5] In comparison, the reported frequency of heterotopic pregnancies in spontaneous conception include 1 in 6778 from Israel,[2] 1 in 4112 from Belgium,[6] and 1 in 3889 from New York.[1] These estimates replace the oft-quoted theoretical incidence of the condition (e.g., 1 in 30,000[7]) determined on the basis of an assumed incidence of 0.37% ectopic pregnancy, and 1 in 15,600[8] on the basis of a 0.8% incidence of ectopic pregnancy. Therefore the risk of a combined pregnancy after IVF–embryo transfer seems to be 30 to 60 times higher than that after spontaneous conception.

The etiologic factors associated with ectopic and heterotopic pregnancies include previous pelvic inflammatory disease, pelvic surgery, associated uterine malformation, use of ovarian hyperstimulation drugs, and multiple embryo transfer. Pelvic inflammatory disease with attendant postinfection tubal damage is evidently a potential etiologic factor in approximately 45% of ectopic pregnancies, raising the incidence by tenfold and even up to 4% of all pregnancies when laparoscopy was used for diagnosis. A 1% incidence of combined intrauterine and extrauterine gestation was found among patients who took ovarian hyperstimulation drugs.[9] The incidence of heterotopic pregnancies would be expected to be high in IVF patients because many have pelvic inflammatory disease, stimulation is used routinely, and multiple embryo transfers are common. The difference in the incidence between our center (1%) and other units (2.9%) could be attributed to the high prevalence of tubal damage and microsurgery among their patients, as discussed by the authors.[4]

The procedure for embryo replacement could raise the chances of combined gestation (e.g., through the direct extrusion of embryos through the tubal ostium by hydrostatic forces).[10] A small volume (50 to 100 μl) of radiopaque dye placed high in the uterus during mock embryo transfer can move into the fallopian tube after a few minutes, then subsequently disappear, possibly by spilling into the peritoneal cavity.[11] Dye was totally or partially transferred into the fallopian tubes in 44% of patients who had a mock embryo transfer in the cycle before IVF. A higher rate of ectopic pregnancy arises if the transfer catheter passes beyond the midcavity, and a routine measurement of the uterine length by

ultrasonography has been recommended to place the embryos in midcavity.[12] Nevertheless, one case of ectopic tubal pregnancy arose despite carrying out embryo transfer under ultrasonographic guidance. Limitation of the volume of transfer medium to 10 to 20 μl may help to avoid ectopic implantation but our present series and the cases reported in Table II show that combined pregnancies can arise with volumes of <10 μl. The number of embryos replaced could also be important; 13 of our 15 patients received three or more, and in other cases the number varied between four and six.[10, 13-16]

Complete tubal occlusion was advocated by Steptoe and Edwards[17] 15 years ago to prevent ectopic pregnancy and this may have helped to reduce the incidence at Bourn Hall Clinic. Fifteen years later tubal occlusions are not performed at Bourn Hall because ultrasonographic oocyte retrieval has reduced the role of laparoscopic assessment before IVF. Bowel adhesions to the tube have occurred after diathermy, making oocyte recovery more difficult, and tubal occlusion will not prevent interstitial pregnancies.

There was a variable clinical presentation among our 17 patients—vaginal bleeding or abdominal pain recurred in nine patients and acute surgical abdominal emergencies in three patients. Five patients did not

have symptoms. The four most common signs and symptoms in heterotopic pregnancies at first examination were earlier reported to be abdominal pain, adnexal mass, peritoneal irritation, enlarged uterus, and the absence of vaginal bleeding in a patient suspected of having an ectopic pregnancy was suggestive of combined gestation rather than an ectopic pregnancy as in our patients, Nos. 1, 3, 4, 5, and 6.

A high index of suspicion of heterotopic pregnancy is required after IVF–embryo transfer. A preoperative diagnosis rate of only 10% has been reported, and a clear-cut ultrasonographic diagnosis before surgical intervention was made in only 14% of cases in a review of the world literature between 1979 and 1984.[18] Transvaginal is superior to transabdominal ultrasonography in the diagnosis of extrauterine pregnancies, and an early diagnosis before rupture offers the chance of therapy in selected cases by ultrasonography-guided aspiration procedures or laparoscopic surgery.

Conservative treatments by aspiration of the gestation sac under ultrasonographic control and an injection of methotrexate[19] or potassium chloride[20] have been reported earlier, and were successful in two patients who progressed to term in the present series, obviating the need for laparotomy or laparoscopy. We restricted aspiration under ultrasonographic control to those patients with fetal heart activity to avoid the misinterpretation of ovarian masses (hemorrhagic corpora lutea cysts) as ectopic pregnancies. Extreme care must be exercised to avoid inadvertent injection of potassium chloride into a maternal vessel, with careful follow-up because the ectopic pregnancy may rupture after treatment with potassium chloride.

A risk-benefit analysis of elective bilateral oophorectomy: Effect of changes in compliance with estrogen therapy on outcome

Theodore Speroff, PhD,[a, b] Neal V. Dawson, MD,[a] Leon Speroff, MD,[c] and Richard J. Haber, MD[d]

Cleveland, Ohio, Portland, Oregon, and San Francisco, California

A bilateral oophorectomy at the time of elective hysterectomy is often performed to prevent ovarian cancer. The assumption that endogenous estrogen can be easily replaced with supplemental medication fosters the decision for routine oophorectomy. Published reports on the use of postmenopausal estrogen indicate that compliance is less than perfect. This fact could affect the overall outcome. Decision analysis techniques with Markov cohort modeling were used to evaluate the policy of elective bilateral oophorectomy. Results from studies judged methodologically sound were combined to determine values representing the influence of estrogen on coronary heart disease, breast cancer, and osteoporotic fracture. The decision tree also explicitly incorporated patient compliance. When compliance with estrogen therapy is assumed to be perfect, oophorectomy yields longer life expectancy than retaining the ovaries. When actual drug-taking behavior is considered, retaining the ovaries results in longer survival. This analysis highlights the importance of including the effects of patient compliance with treatment recommendations when the impact of a health policy decision such as prophylactic surgery is assessed. (Am J Obstet Gynecol 1991;164:165-74.)

Key words: Compliance, bilateral oophorectomy, estrogen therapy, clinical decision analysis

Having decided to undergo hysterectomy, a woman, together with her physician, is faced with the decision of whether to also undergo removal of the ovaries. The proportion of hysterectomies in which both ovaries were removed increased from 25% in 1965 to 41% in 1984.[1] Although elective bilateral salpingo-oophorectomy is performed on >50,000 perimenopausal women each year, wide geographic differences in surgical rates and patterns of physician practice suggest inconsistency in deciding on oophorectomy.[1-7]

A major reason for choosing oophorectomy is to avoid the risk of developing ovarian cancer, a disease known for its poor prognosis.[8-10] Implicit in the argument is the assumption that endogenous estrogen can be easily replaced with supplemental medication.[11, 12] In light of the literature on compliance, assuming perfect compliance with a regimen of estrogen is unwarranted.[13, 14] Less than perfect compliance suggests that the potential effects of estrogen deprivation should also be considered when oophorectomy is contemplated in perimenopausal women.[15-17]

The realization that compliance with estrogen therapy is imperfect and the emergence of new data on the competing benefits and risks of estrogen-related diseases prompted us to reappraise the practice of elective oophorectomy in perimenopausal women. Increased mortality caused by coronary heart disease or hip fracture resulting from estrogen deficiency might combine to offset the benefit derived from avoiding ovarian or breast cancer.[18] In this study a clinical decision analysis explores the implications of changes in both drug compliance and various competing disease risks on the policy of elective oophorectomy.[19]

Methods

The model. The population model consisted of white women undergoing elective hysterectomy. The decision for or against prophylactic bilateral salpingo-

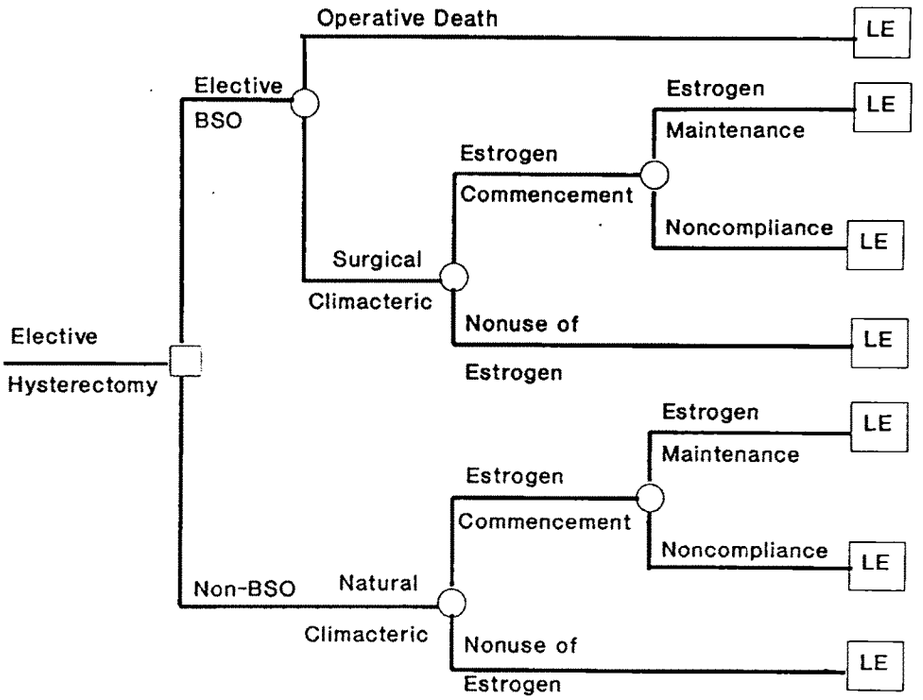

Fig. 1. Decision tree for question of whether to perform elective bilateral salpingo-oophorectomy *(BSO)* at time of hysterectomy. Life expectancy *(LE)* is simulated as a Markov cohort (see text for details).

oophorectomy at the time of hysterectomy divided the population into two groups (Fig. 1). Women who have their ovaries surgically removed submit themselves to a small increase in operative mortality as compared with those undergoing hysterectomy alone. Survivors experience surgical climacteric (i.e., sudden cessation of ovarian production of estrogen), which can be modified by a regimen of supplemental estrogen. Critical to restoring an estrogenic effect is whether exogenous estrogen is started (commencement compliance—estrogen prescribed and taken) and how long the estrogen is maintained (maintenance compliance). The course of events, modified by competing risks associated with estrogen status, is followed for the remaining life span of the patient.

Women who retained their ovaries constituted the alternative treatment strategy; the remaining life span of this nonoophorectomy group is also followed. Women in the nonoophorectomy group will have estrogen production until the time of natural climacteric (i.e., the natural decline in estrogen production by the ovary), which was fixed in this analysis at 50 years of age. A portion will then experience clinical climacteric and some or all will receive estrogen.[20, 21] For prophylactic purposes, some or all asymptomatic women could also receive estrogen. Preliminary evidence suggests that women who suffer clinical menopause have the same susceptibility to the outcomes of interest as those who experience few or only mild menopausal symptoms.[22, 23] The model therefore focuses only on the event of natural climacteric and subsequent use of supplemental estrogen. For either surgical or natural climacteric, the role of compliance (commencement and maintenance of estrogen) is considered. The course of events associated with natural climacteric and nonuse of estrogen is the baseline condition. Between the groups, only the risk for operative death, the risk for ovarian cancer, and the probabilities of estrogen-dependent events are altered.

The life-long course of events is simulated as a Markov cohort.[24, 25] The model allows probabilities of relevant events to differ with time and age. All women are assumed to be well initially and traverse through time until all members of the group die or reach the age of 100 years. Since the duration of temporary disability from a minor event is no longer than 1 year, the cycles were set at 1-year intervals. At each cycle the group traverses through the states of health in relation to the underlying transition probabilities.[24, 25]

During a 1-year cycle, a woman can remain well or experience one of the following adverse events (Table I): (1) spinal fracture, (2) wrist fracture, (3) hip fracture, (4) ovarian cancer, (5) breast cancer, (6) coronary heart disease, or (8) death from hip fracture, ovarian cancer,

90-100	0.040	0.00633	0.03700	0.00038	0.00308	0.00987

breast cancer, coronary heart disease, or other causes. The average number of cycles before death is equivalent to the group's life expectancy and the group with longer expected survival indicates the associated preferred choice of treatment. When morbidity of disease and quality-of-life issues are considered, the group with longer quality-adjusted life years indicates the preferred choice of treatment.

Mortality. The addition of oophorectomy to elective abdominal hysterectomy increases operative mortality. For hysterectomy with oophorectomy, operative mortality is 150% the operative mortality of elective abdominal hysterectomy without oophorectomy.[15] The age-specific (30 to 44 years) surgical mortality rate for low-risk abdominal hysterectomy is 2.8 per 10,000 operations.[34] Thus the incremented operative mortality rate for oophorectomy used in this study was 0.00014.

Mortality is associated with about 10% of the hip fractures that occur in self-sufficient, independently functioning women (Table II). Nonfatal outcomes of hip fracture include extreme loss of function necessitating long-term nursing home care, premanent disability that nevertheless allows independent living, or temporary morbidity followed by full recovery (Table II). A nonfatal hip fracture increases the risk of a subsequent hip fracture (relative risk = 1.6).[42] The outcome of a subsequent fracture depends on the morbidity resulting from the first occurrence, i.e., full recovery, disability, or nursing home care. The likelihood of adverse outcomes increasing with age is represented by an increase in annual incidence rate for fractures (Table I) and by the rate associated with a diminished state of health (Table II).

The annual mortality rates for cancer were modeled with the assumption that survival follows a simple declining exponential function.[43] A 37% 5-year survival rate for ovarian cancer[44] yields an estimated annual mortality rate of 0.1989, and a 75% 5-year survival rate for breast cancer[44] translates into an annual mortality rate of 0.0575. In the model, mortality as a result of cancer was calculated as incremental to the baseline age-specific mortality rate for women.

Table II. Probability of outcome associated with hip fracture

State	Outcome[35-41]			
	Full recovery	Disability	Nursing home care	Dead
Self-sufficient	0.50	0.20	0.20	0.10
Disability		0.44	0.41	0.15
Nursing home care			0.75	0.25

Note: Self-sufficient denotes all states of health from which a first incidence (Table I) of hip fracture can occur. Full recovery means a return to self-sufficiency after hip fracture and thus avoids fracture-related long-term morbidity; however, the relative risk for recurrence increases to 1.6.[42]

A first incidence of coronary heart disease (Table I) was proportioned among angina pectoris, nonfatal myocardial infarction, and fatal myocardial infarction (Table III). With the 10-year survival data reported by Hartunian et al.[33] and the declining exponential function, the annual mortality rate associated with angina was estimated at 0.021 per year. Again with the report by Hartunian et al.,[33] the annual rate for a myocardial infarction was estimated at 0.015 per year. In the model, mortality as a result of coronary heart disease was calculated as incremental to the baseline age-specific mortality rate for women. Given an initial nonfatal myocardial infarction, the subsequent annual risk for recurrent infarction was 0.1412 for women under 65 years of age and 0.2308 for women 65 and older.[33] The probability of death from the recurrent infarction was 0.2938 for women under 65 years of age and 0.6116 for women 65 and older.[33]

To model survival, age-specific mortality rates from life tables for white women were used.[45] The rates were

Table III. First-incidence coronary heart disease events: Proportions of angina pectoris, nonfatal myocardial infarction, and fatal myocardial infarction[33]

Table IV. Reported prevalence of postmenopausal estrogen use

	Commencement (%)*	*Maintenance† (%)*
Bilateral oophorectomy‡	31-89	13-71
Natural menopause§	21-60	5-34

*Commencement denotes proportion of women who receive prescriptions and start taking estrogen.

†Maintenance denotes 5-year compliance to a regimen of estrogen.

‡References 50, 51, 53, 55, 56, 61, and 64 to 67.

§References 50, 53, 55, 56, 64, and 66 to 69.

extended to age 100 by use of Gompertz age-function adjustments.[24, 46] To test our Markov model, the projected life expectancy with our model was compared with the life expectancy reported in the reference tables. With our model we calculated a life expectancy of 45.59 years for a 35-year old woman; the life expectancy reported in the reference tables is 45 years. All calculations were performed with SMLTREE, a decision analysis computer program written for use on an IBM personal computer.[47]

Rates and probabilities. Annual rates of incidence or mortality were converted to transition probabilities by the following formula[25]: Probability = 1 − Exp. (− Rate × Unit of time)

Competing risks associated with estrogen status. The baseline risks for coronary heart disease, breast cancer, and osteoporotic fracture were calculated from information previously published in the medical literature. The values extracted from the literature were estimates of relative risk of disease compared to the baseline condition: natural climacteric and nonuse of supplemental estrogen. The reported risks, weighted by their variance (precision of estimate), were combined to yield a baseline risk and 95% confidence interval.

With natural menopause the preponderance of the literature suggests a decreased risk for coronary heart disease associated with the use of postmenopausal estrogen.[48] The decrease in risk for coronary heart disease from three methodologically sound studies[49-51] was combined to yield a baseline risk of 0.45 (95% confidence interval = 0.33 to 0.61). The risk of osteoporotic fracture also decreases with use of postmenopausal estrogen.[52-54] For our baseline analysis we estimated risk for osteoporotic fracture at 0.54 (95% confidence interval: 0.42 to 0.71). For breast cancer the results from four studies[23, 55-57] indicate no association between breast cancer and postmenopausal estrogen use (risk = 0.93; 95% confidence interval: 0.78 to 1.12). Since the 95% confidence interval surrounds a risk of 1, we set baseline risk for breast cancer at 1.0.

For oophorectomy and no estrogen replacement, we estimated risk of coronary heart disease[49, 58-60] at 2.00 (95% confidence interval: 1.4 to 2.86) and risk of breast cancer[23, 55-57, 61] at 0.60 (95% confidence interval: 0.45 to 0.80). In addition, when no estrogen is taken, oophorectomy starts the progression toward postmenopausal osteoporosis at an earlier age.[62]

In relation to the decision model, estrogen replacement in oophorectomized women counters the elevated risk of coronary heart disease induced by oophorectomy (risk = 1.0) and, if maintained past the age of 50, provides protection (risk = 0.45) against coronary heart disease. Estrogen replacement in oophorectomized women delays the onset of osteoporosis and, if maintained past the age of 50, also provides protection (risk = 0.54) against osteoporotic fracture. However, estrogen replacement in oophorectomized women neutralizes the protection against breast cancer afforded by oophorectomy by returning the risk to a value of 1.0.[63]

Estimates of estrogen use and compliance. Commencement and maintenance constitute important components of estrogen compliance. Commencement denotes the proportion of women who receive prescriptions and start taking estrogen. Maintenance denotes the adherence to a regimen of estrogen over time. Prevalence of commencement and rate of maintenance were abstracted from publications on postmenopausal estrogen (Table IV). Most reports consider 5 years of taking estrogen as a long-term regimen.

For groups of women with oophorectomy, reported commencement of estrogen ranges from a low of 31% to a high of 89%, with 13% to 71% maintaining a long-term regimen. For naturally menopausal women, reported commencement of estrogen ranges from a low of 21% to a high of 60%, with 5% to 34% maintaining a long-term regimen. We assume that women who take estrogen for a long time are less likely to stop than women who have just begun taking it. Therefore maintenance was modeled by a simple declining exponential function with the annual probabilities of dropping out based on the reported 5-year estrogen compliance rate.[43]

Assessment. The full model included the decision

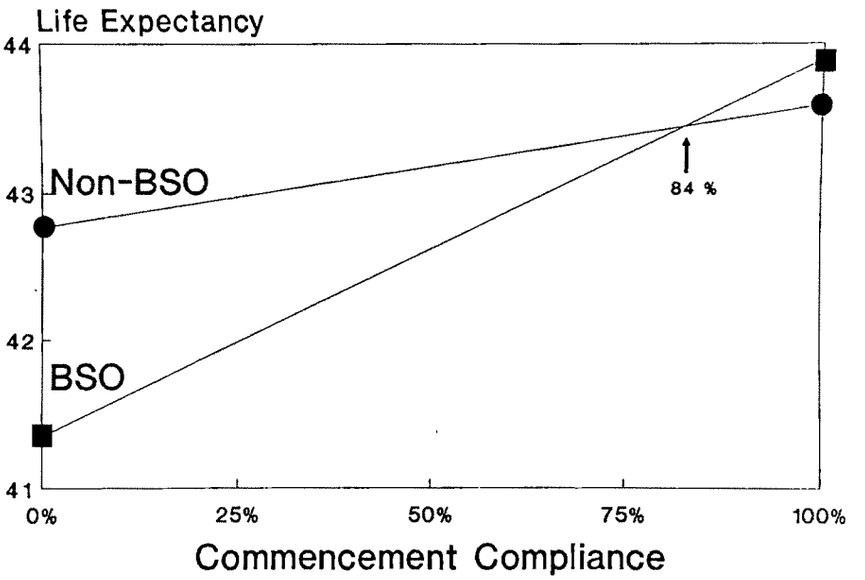

Fig. 2. Effect of oophorectomy *(BSO)* at age 35 and nonoophorectomy *(Non-BSO)* on life expectancy according to proportion of each cohort commencing estrogen therapy. Once estrogen is started, maintenance of estrogen use, as represented here, is perfect life-long compliance. *Filled squares* depict bilateral salpingo-oophorectomy group and *filled circles* depict the nonoophorectomy group.

tree with all competing risks and examined (1) the differences in life expectancy between the policy of oophorectomy versus nonoophorectomy, (2) the effects of variations in commencement and maintenance of estrogen therapy on life expectancy and policy selection, and (3) the effects of age at the time of operation. The ages considered were 35, 40, and 45 years.

Two components of compliance (commencement and maintenance) were varied from 0% (nonuse) to 100% (perfect compliance). This two-way sensitivity analysis on compliance produced a range of life expectancy for each policy (oophorectomy and nonoophorectomy). The range of life expectancy across various levels of compliance was then displayed graphically as a region of life expectancy associated with the chosen policy (oophorectomy or nonoophorectomy). Imposing the published limits of estrogen defined the regions of life expectancy associated with reported estrogen use. The bounded regions of life expectancy for oophorectomy and nonoophorectomy were then compared to identify the treatment with longer expected survival.

Sensitivity analyses were also conducted to verify the robustness of results to quantitative changes in competing risks associated with estrogen status. For the association between estrogen and coronary heart disease, the 95% confidence limits were used. For the association between estrogen and breast cancer, the risk was adjusted up to 2.00 for the nonoophorectomy group taking estrogen. In addition, a present-value analysis was calculated with the use of a discount rate of 5%.[19]

A sensitivity analysis on estrogen-disease relationships was performed by eliminating features from the full model. First, the influence of coronary heart disease was disregarded by setting all estrogen–coronary heart disease risks at 1.0. Second, the influence of breast cancer was also disregarded by setting all estrogen–breast cancer and estrogen–coronary heart disease risks at 1.0. The differences in life expectancy between policies, the effects of variable compliance, and the effects of age at time of operation were assessed in each restricted model.

Reduction in quality of life resulting from morbidity and disability associated with the various states of health was considered by analyzing quality-adjusted life years.[19] The results for quality-adjusted life years were qualitatively the same as the life expectancy results, indicating that considerations of life and death were of primary importance; therefore only the life expectancy results are presented.

Results

The results of Markov simulation on the full model for an operation at 35 years of age are presented in Fig. 2. The vertical axis depicts life expectancy and the left intercept depicts life expectancy associated with nonuse of estrogen (0% commencement). In the absence of estrogen replacement, retaining the ovaries (nonoophorectomy) leads to 1.4 more years of life expectancy than oophorectomy (42.8 years for nonoophorectomy vs 41.4 years for oophorectomy).

In Fig. 2, the proportion of women who start estrogen therapy is varied, while estrogen maintenance is

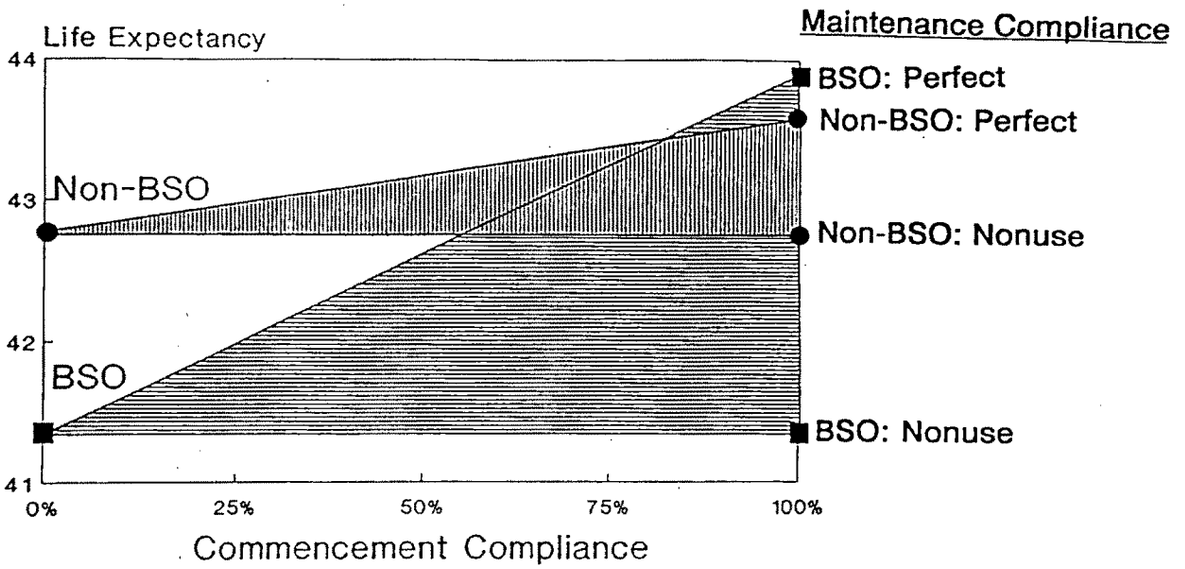

Fig. 3. Effect of oophorectomy *(BSO)* at age 35 and nonoophorectomy *(Non-BSO)* on life expectancy according to all variations in both commencement and maintenance of estrogen therapy. *Filled squares* depict the bilateral salpingo-oophorectomy group and *filled circles* depict nonoophorectomy group. The proportion of women commencing estrogen therapy varies from 0% (nonuse) to 100% along the horizontal axis. Maintenance varies from nonuse of estrogen to perfect life-long maintenance and is labeled along the right vertical axis. For nonoophorectomy the life expectancy resulting from any possible compliance combination (commencement and maintenance) falls within the *triangle* shaded by *vertical lines*. For oophorectomy the life expectancy for any given commencement and maintenance rate falls within the *triangle* shaded by *horizontal lines*.

held constant at 100% (perfect maintenance). Life expectancy increases as the proportion taking estrogen increases from a rate of 0% to 100% commencement. With perfect commencement and maintenance of a life-long regimen of estrogen, a shift in policy occurs. When compliance is perfect, oophorectomy is favored. Shown on the right side of Fig. 2, oophorectomy results in 0.3 more years of life expectancy than retaining the ovaries (43.9 years for oophorectomy vs 43.6 years for non-oophorectomy). The life expectancy lines for the two cohorts intersect at an 84% rate of estrogen commencement. When 84% of the oophorectomy group (at time of operation) and nonoophorectomy group (at time of natural menopause) start and maintain exogenous estrogen, life expectancy is the same for both groups.

In Fig. 3, both components of compliance are varied. Commencement of estrogen extends along the bottom horizontal axis and ranges from 0% to 100%. Maintenance of estrogen extends along the right vertical axis and ranges from nonuse (0%) to perfect compliance (100%) for each group. The borders formed by nonuse of estrogen, perfect life-long maintenance of estrogen, and the right-hand side of Fig. 3 form a triangle for each group (oophorectomy and nonoophorectomy) containing the life expectancies for all variations in drug compliance. For nonoophorectomy the region shaded by vertical lines indicates the life expectancy for every possible combination of estrogen commencement and estrogen maintenance; the region shaded by horizontal lines contains the life expectancy for every compliance possibility for oophorectomy.

Considering the observed lower and upper rates for estrogen commencement and maintenance (reported in Table IV), the shaded regions in Fig. 4 are formed. These shaded areas define a region of life expectancy associated with the published limits of estrogen use. The shaded life expectancy region for the oophorectomy group is below that of the nonoophorectomy group. These findings were replicated for the other ages tested. Thus, within the published limits of estrogen compliance, oophorectomy at the time of hysterectomy leads to a shorter life expectancy regardless of age at time of operation considering the age range of 35 to 45.

Among the modeled diseases, coronary heart disease is by far the most prevalent; it accounts for more than two thirds of the changes in life expectancy, dominates all other consequences, and is clearly the determining factor in the model. A sensitivity analysis on the association between estrogen and coronary heart disease was conducted with the confidence limits that lessen the impact of coronary heart disease (risk = 1.4 for oophorectomy and estrogen nonuse; risk = 0.61 for nonoophorectomy and estrogen replacement). Within the published limits of estrogen compliance, the life-expectancy region for the oophorectomy group re-

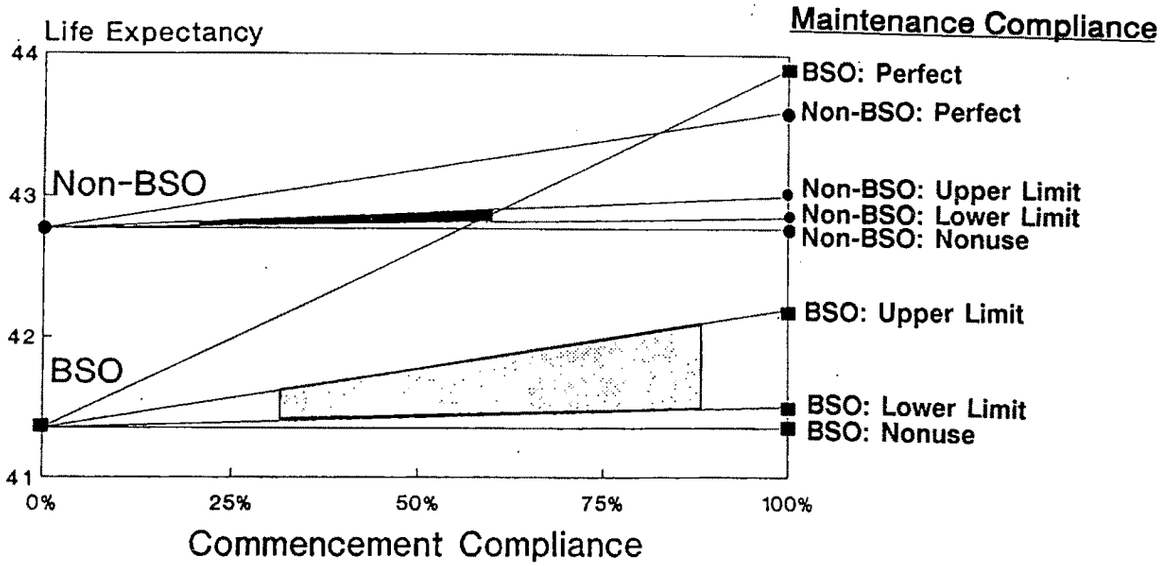

Fig. 4. Effect of oophorectomy *(BSO)* at age 35 and nonoophorectomy *(Non-BSO)* on life expectancy according to published limits of postmenopausal estrogen use. Lower and upper limits of estrogen maintenance reported in Table IV for nonoophorectomy and oophorectomy are labeled along the right vertical axis. The *shaded regions* indicate life expectancy within published limits for commencement and maintenance of estrogen. The *solid black* region indicates life expectancy for nonoophorectomy cohort and the *dot-shaded* region indicates life expectancy for oophorectomy cohort.

mained below that of the nonoophorectomy group at each age tested. Next, the risk of breast cancer associated with estrogen use was modified upward (risk = 2.0). The life-expectancy region for the oophorectomy group again remained below that of the nonoophorectomy group. Throughout sensitivity analysis, nonoophorectomy is the preferred option.

Values estimating the effect of estrogen on the risk of coronary heart disease and breast cancer were chosen from prominent, methodologically sound research. The literature on postmenopausal estrogen use and coronary heart disease, however, has been "controversial"[51, 70] and the literature on postmenopausal estrogen and breast cancer has been "mixed."[71, 72] Some physicians may prefer to disregard the effects of estrogen on these diseases until definitive results are published. For this reason, the decision analysis was repeated, first by disregarding the influence of coronary heart disease on the decision and second by disregarding the influence of both coronary heart disease and breast cancer on the decision.

When coronary heart disease is excluded from the model, breast cancer becomes a determining factor. In modeling, risk of breast cancer was not associated with use of estrogen in the nonoophorectomy group whereas protection against breast cancer was provided by oophorectomy in the oophorectomy group. Thus, regardless of estrogen compliance rates and regardless of age at the time of operation, oophorectomy leads to greater life expectancy than retaining the ovaries when the risk of coronary heart disease is excluded. In sensitivity analysis, adjusting the risk of breast cancer upward for the nonoophorectomy group (risk = 2.0) merely reinforces a preference for oophorectomy.

Excluding the effects of both breast cancer and coronary heart disease from the model, the trade-offs between hip fracture and ovarian cancer were examined. At age 45, the benefits of avoiding ovarian cancer more than offset the consequences of osteoporosis, making oophorectomy the treatment of choice regardless of estrogen use or nonuse. At age 40, oophorectomy remains the preferred approach. At age 35 and within the published limits of estrogen compliance, retaining the ovaries is preferable; a shift from nonoophorectomy to oophorectomy occurs during the late 30s.

A summary of the decisions leading to longer survival is presented in Table V. In addition, the procedure of 5% discounting was applied to each of the above analyses. Discounting favors oophorectomy by giving additional weight to the avoidance of ovarian cancer and breast cancer, which occur relatively earlier in life, and less weight to osteoporotic fracture, which tends to occur late in life. Even with discounting, the qualitative aspects of the findings remain unchanged.

Comment

Decision analysis has been widely applied to technology assessment and is used here to explore the health policy implications of estrogen treatment and elective oophorectomy at the time of hysterectomy.[73]

Table V. Health policy implications

Assessment	*Oophorectomy at time of hysterectomy*		
	35 yr	*40 yr*	*45 yr*
Full model	No	No	No
Coronary heart disease excluded	Yes	Yes	Yes
Coronary heart disease and breast cancer excluded	No	Yes	Yes

The results of the present analysis must be interpreted within the context it considers. For example, competing risks used in the analysis were derived from white women; other racial or ethnic groups may have different estrogen-disease relationships. Certain risk factors such as liver disease, thrombosis, or previous estrogen-sensitive tumor may contraindicate the use of supplemental estrogen; this analysis may not be applicable to women with such conditions. Brands, types, and dosage of postmenopausal estrogens were not differentiated, complex variations such as intermittent estrogen use were not considered, and other simplifying assumptions such as independence among events were made. When combined with estrogen, progestin may decrease risk of breast cancer and counteract the protective effect against coronary heart disease[74]; however, the data are inconclusive and the effects of low-dose progestin in combination with estrogen are just being examined.[75] Furthermore, the current model considered only women who had undergone a hysterectomy. In women without a uterus there is no concern about reducing the negative side effect of spontaneous bleeding that often accompanies estrogen treatment for clinical menopause. For these reasons progestin-estrogen combination medication was not considered in the present analysis.

Three decision analyses have evaluated the postmenopausal use of estrogen and another decision analysis has evaluated the effect of elective hysterectomy.[26, 76-78] Although the magnitude and pervasiveness of noncompliance is generally acknowledged in such evaluations, accounting for noncompliance often plays little or no role in assessment, decision making, policy setting, or individual patient care.[12, 79] Yet, when treatment involves medication, failure to comply can be the determining factor that hinders the goal of health care.[14, 80, 81]

A primary consideration at the time of elective hysterectomy has been the prevention of a future case of ovarian cancer, which is known for its poor prognosis.[9, 10, 15] When coronary heart disease and breast cancer were not considered in the analysis, the net results supported those who advocate routine prophylactic bilateral oophorectomy after the age of 40 years.[9-12, 82] When coronary heart disease alone is disregarded, survival is again greater with the choice of oophorectomy, regardless of estrogen use or nonuse. When coronary heart disease is factored into the model and perfect compliance to exogenous estrogen is assumed, a strategy of oophorectomy is again uniformly favored. The latter analysis, however, neglects the potential effects of variations in compliance with estrogen therapy. When the reported range of compliance with estrogen therapy is factored in the analysis, the preferred strategy changes.

Although consideration of patient behavior adds further uncertainty to the decision process, this added complexity is necessary to realistically compare one clinical strategy or program with another. In this investigation, elective oophorectomy at the time of hysterectomy is not recommended when actual physician prescribing and patient compliance behavior are considered in relation to all relevant estrogen-related diseases. Thus the ultimate decision on oophorectomy may well rely on the individual physician's and patient's assessment of ability to ensure long-term compliance to exogenous estrogen. This finding is in contrast to that based on perfect compliance and demonstrates that treatment based on what is efficacious may substantially differ from treatment based on what is effective.[83]

We are grateful to Randall D. Cebul and the reviewers for their helpful comments and suggestions.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Characterization of sodium channels in cultured human uterine smooth muscle cells

Roger C. Young, MD, PhD, and Lea Herndon-Smith
Charleston, South Carolina

Voltage-clamp studies using the whole-cell patch clamp technique were performed on single cells of cultured human uterine smooth muscle obtained from term pregnancies. The small size of the cells allowed time resolution of transient ionic currents as short as 3 msec. A large, voltage-activated inward current was identified as a sodium channel conductance by the following critiera: (1) Removal of sodium from the bath eliminated the current; (2) current was blocked by the sodium-channel-blocking agent tetrodotoxin; (3) current was observed in the absence of calcium. The sodium current was large (maximal inward current 7.2 $\mu A/cm^2$) and of short duration (decayed within 10 msec). The onset of activation of this current was −40 mV, with peak inward current at −10 mV. Steady-state voltage inactivation of this channel demonstrated half-maximal inactivation at −67 mV, indicating that this channel is largely inactivated at normal resting potentials. (Am J Obstet Gynecol 1991;164:175-81.)

Key words: Human uterine smooth muscle, electrophysiology, voltage-activated sodium channel

Uterine contractions are thought to be regulated largely by the free intracellular concentration of calcium.[1] Depolarization of the membrane is responsible for opening voltage-activated calcium channels,[2] which allows for the influx of calcium from the extracellular space. Any ion channel that modifies the active properties of the cell membrane potentially alters the capabilities of the cell to raise intracellular calcium concentrations.

Sodium conductance effects on action potentials were seen in rat uterine tissue after exposure to neurotoxins[3]; however, voltage clamp observation of a sodium current under physiologic ion concentrations has only recently been reported.[4] Sodium currents have not been previously reported in human uterine smooth muscle. We report here on large, rapidly decaying sodium currents observed in cultured human uterine myocytes under physiologic ion concentrations that are expressions of tetrodotoxin-sensitive, voltage-activated sodium channels.

Material and methods

Cell culture. Small strips of pregnant human myometrium (0.5 × 0.5 × 2.0 cm) were excised from the upper margin of the uterine incision through the lower uterine segment at the time of cesarean delivery (Medical University of South Carolina Institutional Review Board Approval No. 3605). Serosa and endometrium were dissected free and discarded. The myometrium was minced into 1 mm cubes and washed in calcium-magnesium–free Hanks' solution (Sigma Chemical Co., St. Louis). The washed myometrial pieces were placed into a solution composed of calcium-magnesium–free Hanks' solution containing 0.2% (wt/vol) type III collagenase (Worthington Biochemical Corp., Freehold, N.J.), and maintained at 35° C for 30 to 120 minutes until free cells began to appear. The tissue and free cells were then centrifuged at 20 *g* for 5 minutes, the supernatant was discarded, and the pellet was washed in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum, penicillin (100 U/ml, Sigma), and streptomycin (100 μg/ml, Sigma). Aliquots of the suspension were plated into 25ml culture flasks (Corning Medical and Scientific, Medfield, Mass.). The cells were kept in a humidified incubator gassed with 95% air plus 5% carbon dioxide at 37° C in the medium described above. On reaching confluence (usually 7 to 14 days), cells were freed from the flask with 1× trypsin, washed with culture media, and divided into three or four fresh 25ml culture flasks.

Table I. Composition of solutions

	Composition (mmol/L)				
Solution No.	Na^+	K^+	TEA^+	Ca^{++}	Mg^{++}
1	120	5	—	3	—
2	120	5	—	—	3
3	—	5	120	3	—
4	5	110	10	0.1	—

All solutions contain HEPES (5 mmol/L) at pH 7.2, adjusted with potassium hydroxide. Chloride is the counter ion for cations in the table. Solution 4 is the electrode-filling solution and also contains 1 mmol/L EGTA as a calcium buffer. Tetraethylammonium chloride (TEA^+) functions as a potassium-channel-blocking agent in solution 4 and as an inert cation for sodium substitution in solution 3.

Cells used for patch clamp studies were harvested between the third and sixth passage and had been maintained at confluence between 2 and 6 days.

Recording. The myometrial cells were freed from the bottom of the flask with 1× trypsin and 1.5 mmol/L ethylenediaminetetraacetic acid in calcium-magnesium–free Hanks' solution. The cells were washed in media once, followed by three washings with a solution composed of 120 mmol/L sodium chloride, 5 mmol/L potassium chloride, and 10 mmol/L HEPES, pH 7.2 ± 0.05. HEPES is 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid. An aliquot of this solution was placed into the recording chamber and the cells were allowed to settle and adhere to the glass bottom. The recording chamber was then flooded with an electrolyte bathing solution selected from Table I. Cells were observed with a Zeiss Axiovert 35 (Carl Zeiss, Inc., New York) inverted phase-contrast microscope.

Electrodes were pulled on a horizontal puller (Flaming-Brown, Sutter Instruments, San Rafael, Calif.) with borosilicate capillary tubes. Data reported here were obtained with seal resistances of at least 5 GΩ. Electrode resistances ranged from 4 to 7 MΩ when filled with electrolyte solution (solution 4, Table I). Tetraethylammonium chloride (10 mmol/L), a well-known potassium-channel-blocking agent,[5] was used in the electrode solution to reduce outward currents. Ethylene *bis*(oxyethylenenitrolo)tetraacetic acid (EGTA) was used as a calcium buffer to maintain free intracellular calcium concentrations in the nanomolar range.

Patch clamp recordings[6] were performed with the Axopatch 1-B amplifier (Axon Instruments, Foster City, Calif.). A 1 GΩ feedback resistor was used, and data were filtered through a four-pole Bessel filter set at 2 kHz cutoff. After gigaohm seal formation between the patch pipette and the cell membrane, intracellular access was accomplished with either moderate suction on the pipette or high-voltage pulses (1.6 V for several milliseconds).

Data were digitized with the Axolab 1100 data acquisition system and analyzed with p-CLAMP software (Axon Instruments) on a Compaq 286 computer. All recordings were made at 20° to 25° C. Electrode and stray capacitance was electrically compensated. Electrical compensation of the charging currents of the cell membrane capacitance was not used, as minor drift induced large current artifacts in the 1 to 10 msec time frame.

Voltage clamp data were obtained by applying voltage step or voltage ramp commands from the holding potential to test potentials while monitoring the membrane current. By standard convention, positive ions flowing into the cell constitute inward current, which is represented by a downward deflection of current. The magnitude and time course of membrane currents were stable over time (up to 1 hour). Five seconds between test pulses was allowed for the cell to reequilibrate.

Current-voltage curves were obtained by plotting observed currents versus test potentials. Membrane currents were measured from the holding level and, unless specifically noted, were not corrected for leak. Data for inactivation curves were obtained with the double pulse technique—a varying conditioning potential followed immediately by a constant test potential. These currents were corrected for leak before analysis. Curve-fitting of the inactivation curves was performed with a Marquardt nonlinear regression with the aid of STATGRAPHICS software (STSC, Inc., Rockville, Md.). The equation fit was the Hodgkin-Huxley formulation[7] for inactivation:

$$I_{in}/I_{in}(max) = [1 + \exp((V - V_{0.5})/k)]^{-1}$$

Results

Cultured human uterine myocytes exhibit large inward currents under voltage clamp conditions (Fig. 1, *A*). Outward current is reduced with the potassium-channel-blocking agent[5] tetraethylammonium chloride (10 mmol/L) in the electrode. Residual outward currents are apparent (here, 67 pA for the voltage pulse to 0 mV); however, they are small enough to allow clear observation of inward currents. In the presence of both sodium and calcium, two types of inward current can be identified (bath: solution 1). The larger current is a rapidly developing, rapidly decaying inward current with a current-voltage relationship showing the beginning of activation at −30 mV and peak inward current at −10 mV (Fig. 1, *B*). The smaller, more slowing decaying current activates at −40 mV. The peak inward current attributable to this conductance cannot be accurately determined under these conditions since the large fast transient dominates the tracing between −30 and +20 mV.

To determine the ion specificity of these conduct-

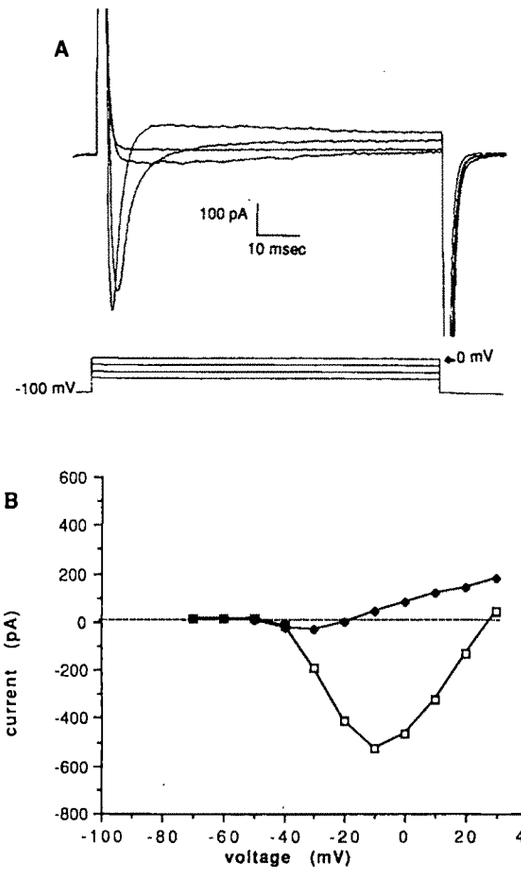

Fig. 1. A, Inward current recorded from cultured human myometrium with whole-cell voltage-clamp technique. Bathing solution contains 120 mmol/L sodium and 3 mmol/L calcium (solution 1). Lower tracing shows voltage paradigm. Holding potential is −100 mV. Four test pulses from holding to −30, −20, −10, and 0 mV are shown. **B**, Current-voltage relationship for peak inward current (□) and inward current that persisted longer than 20 msec (■).

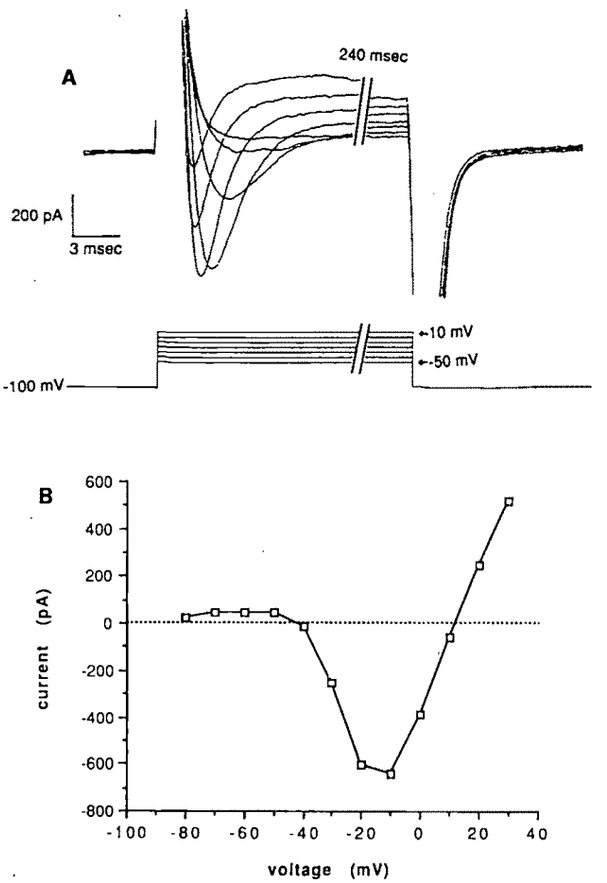

Fig. 2. A, Inward sodium currents observed with calcium-free bathing solution (solution 2). **B**, Current-voltage relationship for peak inward currents.

ances, ion substitution experiments were performed. Fig. 2, *A*, shows the current tracings obtained when magnesium is substituted for calcium (bath: solution 2). The large, fast transients persist, but the slower transients are not apparent. The current-voltage relationship of the peak inward current under these conditions (Fig. 2, *B*) is only slightly different than the current-voltage relationship obtained in the presence of calcium (Fig. 1, *B*). The onset of activation is −40 mV and the peak inward current is −10 mV in this calcium-free solution.

Fig. 3 is a comparison of current responses of the same cell under differing bathing compositions. From a holding potential of −100 mV, a test voltage of −10 mV was applied after exchange of bathing solution. Tracing a was obtained in the presence of both sodium and calcium (bath: solution 1) and is composed of a fast and a slow component. Tracing b was obtained after exchange of bathing solution 1 with a solution that did not contain calcium (bath: solution 2). Under these conditions, the fast transient persists, but the slow transient is much reduced. The 1 msec difference in time-to-peak current is a result of a small loss of time resolution that occurred during solution change. Exchange of the bathing solution with one that contains calcium but no sodium (bath: solution 3) yields tracing c, where the slow transient is observed but the fast transient is not. This experiment demonstrates the dependence of the fast transient on the presence of sodium, but not on the presence of calcium, and implies that the fast transient is the expression of a sodium channel.

Confirmation of the fast transient as a sodium channel current can be made by investigation of the sensitivity of the fast transient to tetrodotoxin, a specific sodium-channel-blocking agent.[8] The rapidly decaying inward current is lost as the tetrodotoxin concentration

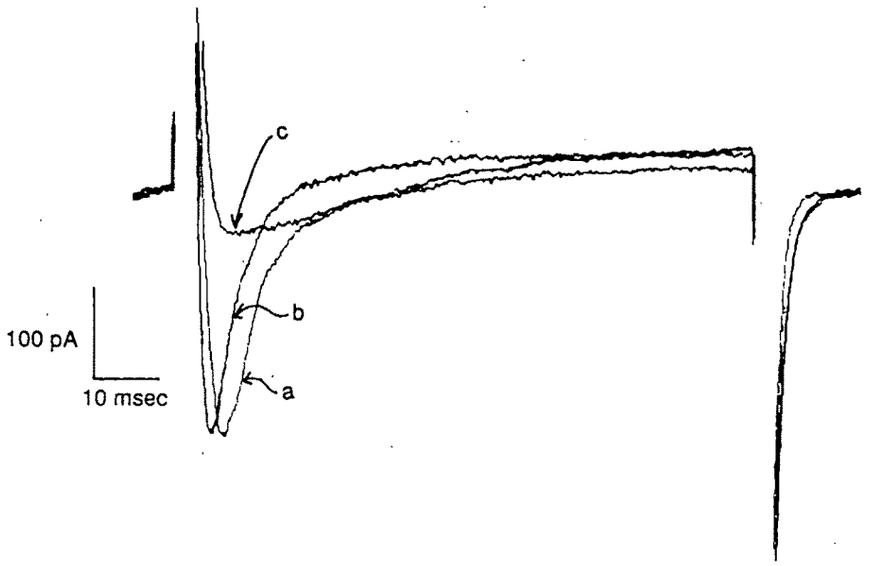

Fig. 3. Overlay of current responses resulting from identical test pulses from −100 to −10 mV on the same cell but with different bathing solutions. *a*, Solution 1 (sodium and calcium present). *b*, Solution 2 (sodium present, calcium absent). *c*, Solution 3 (sodium absent, calcium present).

is increased to 1 μmol/L and returns on rinsing the experimental chamber with tetrodotoxin-free bathing solution (Fig. 4).

The capacitance of the cell may be measured by applying a voltage ramp under voltage clamp conditions. The voltage ramp rises from −100 to +50 mV over 70 msec and then returns to a −100 mV holding potential. The step increase in current at the beginning of the ramp (Fig. 5, arrow) relates to the charging of the membrane capacitance by the relationship $\Delta i = Cm \times \Delta V/\Delta t$, where Cm is the membrane capacitance and $\Delta V/\Delta t$ is the magnitude of the voltage ramp applied (in this case 2.14 V/sec). The observed current step in Fig. 5 is 186 pA, which corresponds to a capacitance of 87 pF for this cell in solution 2. Assuming a 1 $\mu F/cm^2$ unit membrane capacitance, the cell membrane surface area is 8.7×10^{-7} cm^2. Changing bathing solutions from solutions 1 through 4 in Table I did not significantly affect the observed values of membrane capacitance. For a peak inward current of 630 pA (Fig. 2, *B*), the current density is calculated to be 7.2 $\mu A/cm^2$. The downward inflection of the current in response to the rising voltages (Fig. 5) yields a quasi-steady-state current-voltage relationship that is qualitatively similar to the peak inward current-voltage relationship obtained with the repetitive voltage pulse technique (Fig. 2, *B*).

The sensitivity of the sodium current to changes in the resting membrane potential can be demonstrated by a double-pulse experiment, where a conditioning voltage is applied for 250 msec, followed by a test pulse to 0 mV (Fig. 6, *A*). As the conditioning pulse becomes more depolarizing, the inward current induced by the test pulse is reduced. The resulting inactivation curve (Fig. 6, *B*) is well fit by the Hodgkin-Huxley formulation of a Boltzmann distribution curve yielding $V_{0.5} = -67$ mV and $k = 8.5$ mV. The bathing solution for this experiment was chosen to be as close to physiologic ion concentrations as possible. Specifically, calcium was not omitted. Since calcium currents are much smaller than the sodium currents, errors in the Boltzmann parameters caused by calcium currents are minimal.

Comment

This work describes a fast, voltage-activated sodium channel that is expressed in cultured human uterine myocytes. Ion substitution experiments demonstrate that sodium in the bathing solution is necessary for the expression of the rapidly decaying transient; however, calcium is not. Furthermore, the fast current is sensitive to micromolar concentrations of the sodium-channel-blocking agent tetrodotoxin.

For nerve tissue, tetrodotoxin typically ablates sodium channels at concentrations in the nanomolar range, where cardiac muscle,[8, 9] skeletal muscle,[8, 10] and rat uterine smooth muscle[4] sodium channels require 1 μmol/L for total block. Since the cultured human myometrial cells described here similarly require 1 μmol/L tetrodotoxin for block, they are tetrodotoxin

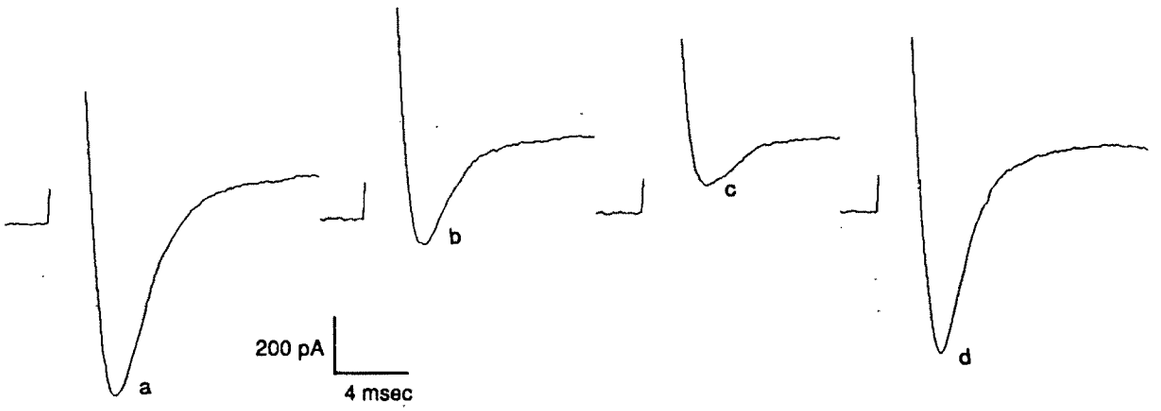

Fig. 4. Sodium current responses to increasing concentrations of tetrodotoxin, followed by washout of bath with tetrodotoxin-free solution (*a*, 0; *b*, 10^{-7} mol/L; *c*, 10^{-6} mol/L; *d*, washout). Bath: solution 2. Test pulses are from holding potential of −100 to −10 mV.

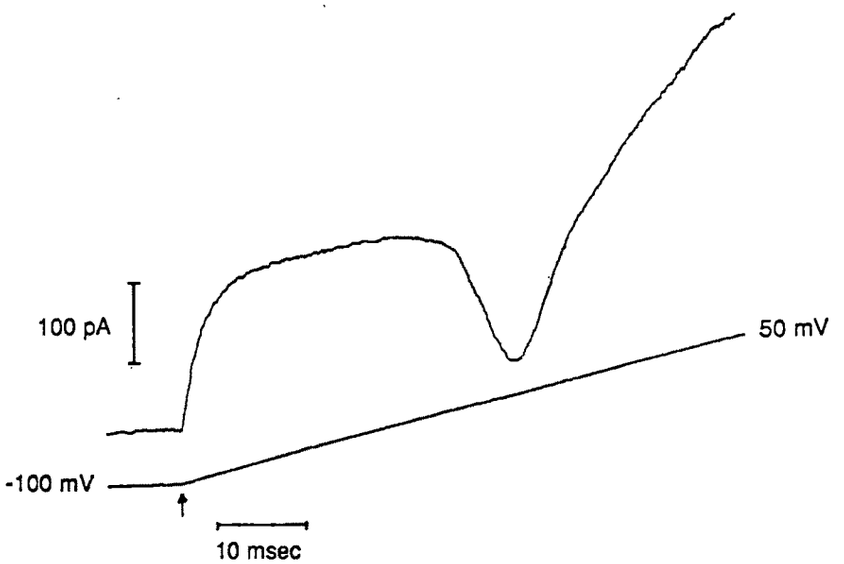

Fig. 5. Under voltage clamp conditions, a 70 msec voltage ramp is applied from holding potential (−100 mV) to +50 mV. *Arrow* marks onset of voltage ramp. Current needed to fully charge membrane capacitance is 186 pA, yielding a membrane capacitance of 87 pF (see text).

sensitive. Persistence of tetrodotoxin sensitivity of sodium channels in these cells, which have undergone at least three passages in culture, is in contrast to reports on cultured cardiac[9] and denervated skeletal[10] muscle, where tetrodotoxin sensitivity was rapidly lost.

Recently Ohya and Sperelakis[4] reported a sodium channel in myocytes freshly isolated from uteri of pregnant rats. They reported a maximum current density of 1.64 μA/cm² for the sodium channel in comparison to 7.2 μA/cm² seen here for cultured human myocytes. The relatively large value for peak sodium current is actually a lower limit, since the time resolution of our experiment is at best 3 msec, and the sodium current transient has a half-life of 2 to 4 msec. In other respects the similarity of the sodium channels is remarkable (Table II).

Inoue et al.,[11] in freshly isolated myometrium from human pregnancy, failed to observe a voltage-activated sodium current. The time resolution of the current tracings in the whole-cell voltage-clamp experiments is not reported and may not have been sufficient for resolution of the fast sodium current. However, in that report the resting membrane potential did vary with external sodium concentration.

The physiologic role of the sodium channel is not immediately apparent. The resting potential of freshly dispersed myometrial cells from human pregnancy has been measured with intracellular microelectrode tech-

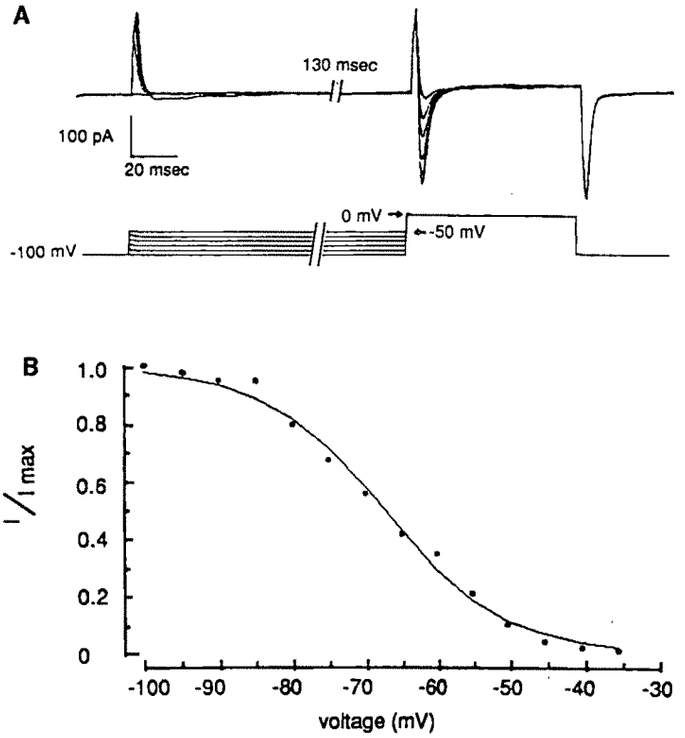

Fig. 6. A, Current responses to test pulse to 0 mV after various conditioning pulses (see Methods). Bath: solution 1. Conditioning pulse duration is 250 msec. **B**, Hodgkin-Huxley inactivation curve of peak inward current. Nonlinear regression of data *(solid line)* yields $V_{0.5} = -67$ mV, $k = 8.5$ mV.

Table II. Comparison of electrophysiologic parameters between sodium channels of rat[4] and human myometrium (this work)

	Activation (mV)		*Inactivation (mV)*	
	Onset	*Peak*	$V_{0.5}$	k
Rat	−40	0	−64	7.1
Human	−40	−10	−67	8.5

Data on rats were obtained on freshly dispersed uterine cells from pregnant rats, whereas data on human cells were obtained from cultured uterine myocytes. Both sets of activation data were obtained in calcium-free solutions with inactivation data obtained in physiologic calcium solution.

niques to be around −50 mV, although there was a large amount of cell-to-cell variability.[11, 12] At this potential and under physiologic ion concentrations (bath: solution 1), the sodium channels are significantly inactivated (Fig. 6, *B*). More important, the inactivation of the sodium channel required a conditioning pulse duration of only 250 msec (Fig. 6, *A*), which was specifically chosen to be of shorter duration than slow-wave membrane potential changes. Thus, as a slow wave depolarizes the cell to the potential at which calcium channels begin to open (approximately −40 mV),[11] the sodium channels will be largely inactivated and will not likely contribute to the rising spike of the action potential. This reasoning is in agreement with our observation that substitution of half of the extracellular sodium with tetraethylammonium chloride fails to reduce the maximal rise of the action potential spike in freshly dispersed human uterine myocytes.[13] Thus sodium currents cannot be demonstrated to significantly contribute to the rising phase of the action potential in human myocytes.

Trypsin was used to release the cells from the culture flasks and may have modified the activation or inactivation properties of the channel.[14] The close agreement of the electrical properties of the sodium channels of these human cells with those found for the sodium channels of rat uterine cells isolated with the use of collagenase[4] argues against significant channel modification by enzymes.

Whenever possible, conditions were chosen to minimize deviations from physiologic conditions. For example, suppression of outward currents was found to be adequate with the use of only 10 mmol/L tetraethylammonium chloride in the electrode solution, although harsher conditions such as total replacement of intracellular potassium are more effective. The use of

cesium (a potent potassium-channel-blocking agent) was attempted but abandoned because of cell destruction after approximately 10 minutes of experimentation.

We chose a 250 msec duration for the conditioning pulse in the double-pulse sodium-channel inactivation experiment rather than the usual duration of several seconds[14] to determine that inactivation occurs on a time scale that is shorter than that of uterine slow-wave depolarization. Additionally, 3 mmol/L calcium was used in the sodium-channel inactivation experiment to prevent adverse effects of nonphysiologic calcium solutions.[15]

Cultured human uterine cells seem to be an appropriate model system for the study of ion channels of human myometrium. The improved time resolution inherent to the smaller cell size allows quantitative characterization of the fast sodium channel by means of single-electrode techniques.

Cocaine directly augments the α-adrenergic contractile response of the pregnant rabbit uterus

William W. Hurd, MD,[a, b] Patricia A. Robertson, MD,[a] R. Kirk Riemer, PhD,[a, b] Alan Goldfien, MD,[a, b] and James M. Roberts, MD[a, b]

San Francisco, California

Cocaine use in pregnancy is associated with a premature labor rate as high as 50%, but little is known about its effect on uterine contractility. To determine whether cocaine directly augments pregnant uterus contractility, uterine strips from 27-day pregnant New Zealand White rabbits (term, 31 days) were exposed to cocaine alone (30 μmol/L) or cocaine plus epinephrine (10^{-9} to 10^{-5} mol/L) or oxytocin (10^{-10} to 10^{-6} mol/L). Cocaine alone produced no contractions, but increased the epinephrine sensitivity by 51% and the maximal response by 33%. When β-adrenoceptors were blocked with DL-propranolol (2 μmol/L), the contractile response to epinephrine was increased, and cocaine's effect was blocked. In the presence of the stereoisomer D-propranolol (2 μmol/L) with no β-adrenergic antagonist activity, the contractile response to epinephrine was unchanged, but the effect of cocaine was still blocked. We conclude that cocaine directly augments the α-adrenergic contractile response of the pregnant rabbit uterus by a mechanism that is blocked by the non-β-adrenergic effects of propranolol. (AM J OBSTET GYNECOL 1991;164:182-7.)

Key words: Cocaine, pregnancy, propranolol, premature labor, drug abuse, catecholamines, adrenergic receptors

Drug abuse has become a major health concern in the United States, involving an estimated 15% of women of childbearing age.[1] The use of cocaine has been found to be especially deleterious during pregnancy, where it is associated with, among other things, a premature labor rate of 17% to 50%.[2-4] Unfortunately, little is known about how cocaine might affect uterine contractility and thus predispose pregnant women to premature labor.

Although cocaine may augment uterine contractility by a systemic effect such as increased circulating catecholamines,[5] direct effects of cocaine on the uterus may be at least as important. Cocaine is known to augment the contractile response to several agonists, most notably catecholamines, in many different types of muscles.[6-10] In addition, cocaine alone has been reported to directly induce contractions in nonpregnant uteri of rabbits and rats,[11, 12] although other investigators have found no contractile effect of cocaine alone.[13]

The best characterized mechanism by which cocaine augments contractile response is inhibition of catecholamine uptake by sympathetic nerve endings, thus increasing the local concentration of catecholamines.[14] However, because the pregnant uterus has few functioning adrenergic nerve endings after midpregnancy,[15, 16] inhibition of neuronal uptake is unlikely to play a significant role in the association of cocaine with premature labor. Cocaine has also been shown to potentiate the α-adrenergic contractile response of tissue known to be free of sympathetic innervation such as human umbilical artery.[6] This could be a result of either a selective effect on α-adrenoceptors or a general effect on smooth muscle that increase contractility.[6]

This study was designed to answer the following two questions. First, does cocaine, alone or in conjunction with other agonists, augment the contractility of the pregnant rabbit uterus. And second, is cocaine's effect selective for the α-adrenergic contractile system rather than a more general effect on uterine contractility. To address these questions, we studied the effect of cocaine on the in vitro contractile response of the pregnant rabbit uterus both alone and in the presence of epinephrine, oxytocin, or potassium chloride. The epinephrine response was further characterized by the addition of the β-adrenoceptor antagonist DL-propranolol and the stereoisomer D-propranolol, which does not block β-adrenoceptors.[17]

The results of this study indicate that in our system, cocaine alone has no direct contractile effect on the pregnant rabbit uterus but augments the α-adrenergic

contractile response of the uterus by a selective mechanism that is blocked by the non-β-adrenergic effects of propranolol.

Material and methods

Animals and tissue preparation. Timed-pregnant New Zealand White rabbits (White Hare Rabbitry, Stark City, Mo.) weighing 2.7 to 3.2 kg were cared for under the guidelines of the University Animal Care Facility. At 27 days' gestation (term, 31 days) the rabbits were given lethal intravenous injections of pentobarbital (50 mg/kg) and portions of the uteri were quickly removed and placed in Krebs solution.

Drugs. The drugs used were epinephrine and DL-propranolol (Sigma Chemical Co., St. Louis), oxytocin (Calbiodem Co., La Jolla, Calif.), D-propranolol (Ayerst Laboratories, New York, N.Y.), and cocaine hydrochloride (pharmaceutical grade). All drugs were dissolved in 1 mmol/L hydrochloric acid.

Evaluation of contractile activity. Contractile activity was determined as previously described.[13] Briefly, portions of the uteri were trimmed of excess fat and connective tissue and cut into uniform longitudinal 12 mm × 3 mm strips. These strips were then suspended in 20 ml tissue baths filled with Krebs solution (composition in millimoles per liter: sodium chloride, 118.3; potassium chloride, 4.7; calcium chloride, 2.5; magnesium sulfate, 1.18; potassium hypophosphate, 1.17; sodium bicarbonate, 25.0; and glucose, 11.1) aerated with 95% oxygen and 5% carbon dioxide (pH 7.4) at 37° C. The strips were allowed to equilibrate at 2 *g* tension for 1 hour, during which time the Krebs solution was replaced every 30 minutes. Isometric contractile activity was measured with force transducers (Grass Instruments, Quincy, Mass.). Data were digitized at a rate of 60 points per minute and recorded on a magnetic disk by microcomputer (Apple Corporation, Cupertino, Calif.). Replicate strips from each rabbit were averaged to obtain a mean response for each experimental condition. Contractile force was quantified by integrating the area under the tension versus time curve for 90 seconds after addition of each agonist dose.

Protocol. The effect of cocaine alone was determined by exposure of uterine strips to cocaine hydrochloride (30 μmol/L) and recording contractile activity both immediately and after 30 minutes of continuous exposure. To determine the effect of cocaine on the contractile response to other agonists, immediately after the addition of cocaine hydrochloride (30 μmol/L), the strips were exposed to increasing concentrations of epinephrine (10^{-9} to 10^{-5} mol/L) or oxytocin (10^{-10} to 10^{-6} mol/L) every 90 seconds to generate cumulative concentration-response curves. The effect of cocaine on receptor-independent contractility was evaluated by exposure of fresh strips to a single depolarizing dose of potassium chloride (70 mmol/L) immediately after the addition of cocaine hydrochloride (30 μmol/L). To determine whether the effect of cocaine on the adrenergic contractile response was a result of an interaction with the β-adrenergic contractile mechanism, β-adrenoceptors were blocked by pretreatment for 30 minutes with DL-propranolol (2 μmol/L) before exposure to increasing concentrations of epinephrine (10^{-9} to 10^{-5} mol/L). To determine whether propranolol's ability to block the effects of cocaine was a result of β-adrenergic antagonism or to other effects of propranolol, DL-propranolol was replaced with D-propranolol, the stereoisomer of propranolol with no β-adrenergic blocking ability,[17] and the experiment was repeated.

Data analysis. Cumulative concentration-response curves were compared in terms of sensitivity (EC_{50}) and maximal contractile response (E_{max}). EC_{50}, defined as the concentration of agonist necessary to elicit a response equal to 50% of the maximal response, was calculated graphically for each uterine strip and the results were averaged for each rabbit. E_{max}, defined as the greatest integrated area under the force versus time curve developed during a concentration-response experiment, was expressed as a percentage of the maximal response to epinephrine alone. EC_{50} and E_{max} values were compared by a two-way analysis of variance followed by Duncan's multiple range test. A value of $p < 0.05$ was considered significant. Data are presented as the mean ± the SEM.

Results

Cocaine alone did not produce contractions in uterine strips from 27-day pregnant rabbits either acutely or at any time during a 30-minute observation period (Table I). However, cocaine did decrease the EC_{50} to epinephrine by 51% (Figs. 1 and 2, *A*) and increased the E_{max} to epinephrine by 33% (Figs. 1 and 2, *B*). Cocaine had no effect on the E_{max} to oxytocin or potassium chloride depolarization (Table I). Nor did cocaine have an effect on the EC_{50} to oxytocin (control, 4.9 ± 1.8 nmol/L; with cocaine, 6.9 ± 3.6 nmol/L).

When β-adrenoceptors were blocked with DL-propranolol (2 μmol/L) before epinephrine stimulation, the EC_{50} was decreased by 31% (Fig. 2, *A*), and E_{max} was increased by 43% (Fig. 2, *B*). The addition of cocaine prevented the increase in both sensitivity and maximal response. When DL-propranolol was replaced with the stereoisomer D-propranolol (2 μmol/L), the epinephrine response was not altered (Fig. 2). However, cocaine's ability to augment epinephrine sensitivity and maximal response was still prevented.

Comment

The results of this study indicate that whereas cocaine alone has no direct contractile effect on the pregnant rabbit uterus, it does augment the α-adrenergic con-

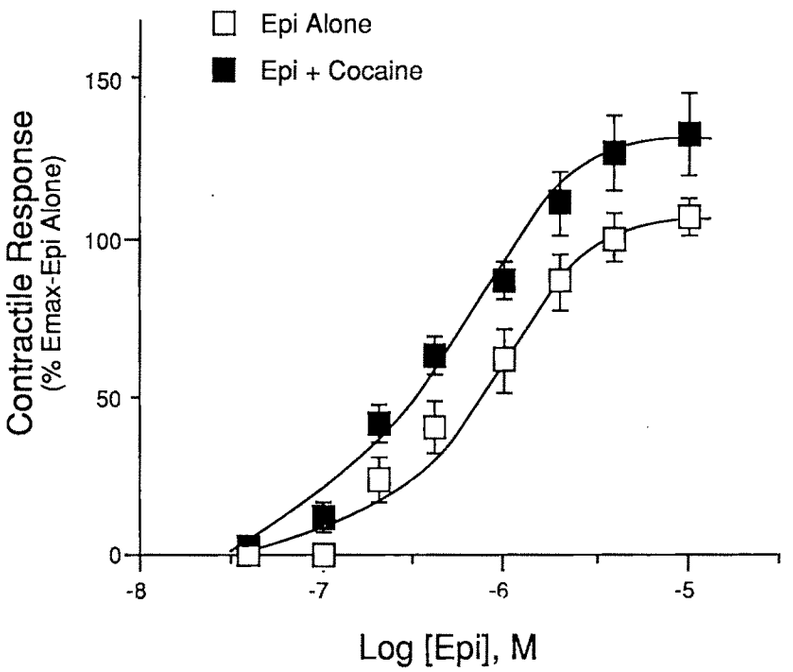

Fig. 1. Concentration-response curve for epinephrine with or without cocaine. Duplicate uterine strips from 27-day pregnant rabbits were exposed to increasing concentrations of epinephrine (10^{-9} to 10^{-6} mol/L) either alone *(Epi Alone)* or in presence of 30 μmol/L cocaine hydrochloride *(Epi + Cocaine)*. Data are expressed as percentage of maximal response to epinephrine alone (mean ± SE); $n = 8$ rabbits.

Oxytocin	10	Immediately	7	88 ± 13	77 ± 9

Data are expressed as mean ± SE.

tractile response of pregnant rabbit uterus by a selective mechanism that is blocked by the non-β-adrenergic blocking effects of propranolol. When both α- and β-adrenoceptors are stimulated by epinephrine, cocaine increases the E_{max} by >50% and increases the sensitivity (i.e., decreases the EC_{50}) by >30% (Figs. 1 and 2). This effect seems to be selective for the adrenergic system because cocaine had no effect on the contractile response to either oxytocin or potassium chloride depolarization (Table I).

It was somewhat surprising to find that cocaine alone has no direct contractile effect on the pregnant rabbit uterus inasmuch as cocaine has been reported to induce contractility in the nonpregnant estrogen-treated rabbit uterus with an EC_{50} of 25 μmol/L.[11] However, in previous studies conducted in our laboratory, cocaine hydrochloride (20 μmol/L), used to prevent neuronal uptake of catecholamines by uterine strips from nonpregnant estrogen-treated rabbits, did not induce contractility.[13] Perhaps this lack of response to cocaine alone is a result of subtle differences in our experimental conditions.

Cocaine's ability to augment the adrenergic contractile response was further characterized by the addition of DL-propranolol or D-propranolol. In an effort to determine whether cocaine's effect was on the α-adrenergic contractile system, the tissue was incubated with the β-adrenergic antagonist, DL-propranolol (2

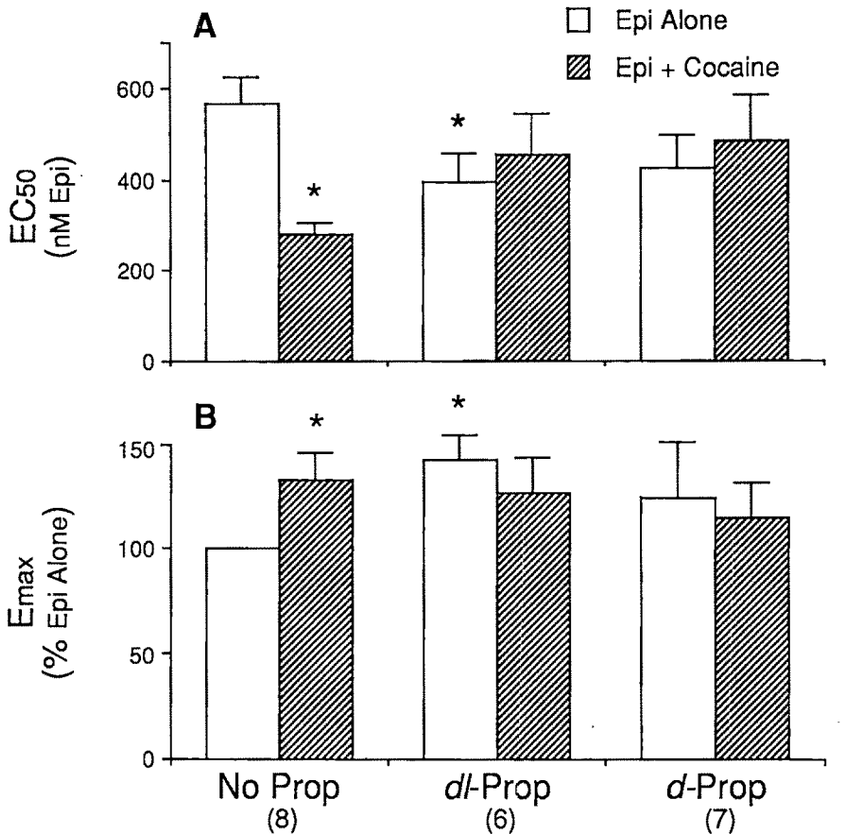

Fig. 2. A, Contractile sensitivity (EC 50) and **B,** maximal contractile response (E_{max}) for epinephrine. Duplicate uterine strips from 27-day pregnant rabbits were exposed to increasing concentrations of epinephrine (10^{-9} to 10^{-6} mol/L) either alone *(Epi Alone)* or in presence of 30 μmol/L cocaine hydrochloride *(Epi + Cocaine)*. Before epinephrine exposure, strips were equilibrated for 1 hour alone *(No Prop)*, in presence of 2 μmol/L DL-propranolol *(DL-Prop)*, or in presence of 2 μmol D-propranolol *(D-Prop)*. Data are average EC 50 (nmol/L epinephrine) determined graphically **(A)** or the average E_{max} expressed as percentage of maximal response to epinephrine alone **(B)** from concentration-response curves including those depicted in Fig. 1. Data are expressed as mean ± SE with number of rabbits indicated in parentheses. (*$p < 0.05$ versus epinephrine alone, no propranolol.)

μmol/L). The ability of DL-propranolol to increase both the sensitivity and the maximal response (Fig. 2) was expected because β-adrenoceptor stimulation results in uterine relaxation. But the loss of cocaine's ability to increase either sensitivity or maximal response was unexpected. On first evaluation, this seemed to indicate that cocaine may work by interfering with β-adrenergically mediated relaxation. To further clarify this observation, DL-propranolol was replaced with the stereoisomer D-propranolol (2 μmol/L), which does not block β-adrenoceptors.[17] As was expected, the epinephrine response was not altered. But in addition, cocaine's ability to augment epinephrine sensitivity and maximal response was also prevented (Fig. 2). This finding suggests that cocaine augments contractility by an effect on the α-adrenergic system, which can be blocked by the non-β-adrenergic effects of propranolol. This effect of cocaine and the ability of D-propranolol to inhibit it could be further characterized by the use of a pure α-adrenergic agonist (e.g., methoxamine hydrochloride) and this approach will be used in future studies.

Propranolol has been well established to have membrane-stabilizing properties in cardiac muscle that does not involve the adrenergic system.[17] This quinidine-like local anesthetic property of propranolol results in both decreased membrane responsiveness and decreased action-potential amplitude as well as decreased excitability and action potential velocity.[18] Because D-propranolol retains membrane-stabilizing ability but has no β-adrenoceptor blocking activity,[17] membrane stabilization may be the way in which propranolol blocks cocaine's ability to augment the α-adrenergic contractile effect.

The ability of propranolol to block cocaine's aug-

mentation of the α-adrenergic response may explain both experimental and clinical observations made when cocaine was evaluated in the presence of propranolol. First, cocaine has been found to augment adrenergic contractility in several denervated tissues if propranolol is not used.[6-8] However, when propranolol has been used to block β-adrenoceptors, no effect of cocaine is seen.[9, 10] Of more interest is the finding that propranolol has been found to decrease the mortality associated with cocaine use in several species including human beings,[19, 20] presumably by prevention of hyperstimulation of β-adrenoceptors in the heart and thus avoidance of tachyarrhythmias. Perhaps propranolol's non-β-adrenergic effects account for some of its ability to block cocaine effects in vivo.

Although this study indicates that cocaine augments the contractile response of the pregnant uterus by a direct effect, cocaine could predispose the pregnant uterus to premature labor by indirect mechanisms. Cocaine is best known for its complex actions on the central nervous system where, among other things, cocaine increases catecholamine and acetylcholine levels.[21] Because both catecholamines and acetylcholine stimulate the release of oxytocin,[22] cocaine may increase uterine contractility by increasing the level of circulating oxytocin. Unfortunately, no information is available on the effects of cocaine on oxytocin release.

Alternatively, it has been postulated that cocaine might predispose the pregnant uterus to premature labor because of its known ability to increase circulating levels of epinephrine and norepinephrine.[1, 5] However, available evidence suggests that increased levels of circulating catecholamines may actually inhibit contractility of the pregnant uterus. When epinephrine is administered during human labor, coordinate uterine activity is diminished.[23] Conversely, when norepinephrine is administered, only incoordinate uterine activity is increased.[23] Furthermore, when epinephrine and norepinephrine are increased during labor as a result of maternal anxiety, the length of labor is actually increased, suggesting an inhibitory effect of increased catecholamines on uterine contractility in vivo, probably mediated through β-adrenoceptors.[24] However, the direct effects of cocaine shown in our study may convert the net effect to an increase in uterine contractility when circulating levels of epinephrine and norepinephrine are increased by cocaine use.

The degree to which the results of this study may apply to the use of cocaine by pregnant women is uncertain because of possible interspecies differences and because of the cocaine concentration studied. Although adrenoceptor function is believed to be similar in the rabbit and the human uterus,[13] no previous study of which we are aware has addressed the effect of cocaine on the pregnant uterus of either species. Furthermore, the concentration of cocaine used in this study (30 μmol/L) is approximately 10 times the serum concentration associated with smoking alkaloidal "crack" cocaine[14] and thus may not reflect the condition seen in human cocaine users. However, the results do suggest that cocaine may selectively augment the contractile response of the pregnant uterus to α-adrenergic stimulation.

These data also have important implications for experimental design. Studies of adrenergic responses of smooth muscle in vitro are characteristically performed in the presence of cocaine to block neuronal uptake.[13] Conversely, the effects of cocaine are often studied in the presence of propranolol to selectively evaluate the α-adrenergic response.[9, 10] This study shows that not only can the effects of propranolol be masked by cocaine in vitro but also that the effects of cocaine can be masked by propranolol. (Fig. 2).

In summary, this study showed that cocaine alone has no direct contractile effect on the pregnant rabbit uterus, but that it augments the α-adrenergic contractile response by a selective mechanism that can be blocked by the membrane-stabilizing effects of propranolol. This information raises the possibility that the increased rate of premature labor associated with cocaine use in pregnancy may be related to direct effects of cocaine on the pregnant uterus.

Special thanks to Mureen Schlueter, MS, and Cindy Brown, BS, for assistance in tissue acquisition.

Spontaneous and steroid-induced recurrence of endometriosis after suppression by a gonadotropin-releasing hormone antagonist in the rat

Kathy L. Sharpe, PhD, Maria C. Bertero, MD, Kenneth N. Muse, MD, and Michael W. Vernon, PhD

Lexington, Kentucky

Recurrent endometriosis in women is difficult to study because of the ethical consideration of performing repeated surgeries. Previously in the rat model we described therapeutic regression of endometriosis with the gonadotropin-releasing hormone antagonist antide. Presently we report the spontaneous and steroid-induced recurrence of endometriosis after withdrawal from antide therapy. Rats with endometriosis received antide or vehicle on days 0 (proestrus), 3, 6, and 9 and were killed on days 0, 6, 12, 18, 24, 30, and 42 (n = 4 antide-treated and 4 vehicle-treated rats killed per day). Additional antide-treated rats (n = 4 per treatment) received estrogen, progesterone, both estrogen and progesterone, cholesterol, and no steroid on day 9 and were killed on day 12. Antide significantly suppressed endometriotic implant size on days 12, 18, and 24. However, implant size spontaneously returned to pretreatment values by day 30. Administration of steroids on day 9 elicited regrowth of antide-suppressed endometriosis (estrogen plus progesterone greater than estrogen, progesterone, or cholesterol greater than no steroid) by day 12. This resilience of endometriosis offers an explanation for treatment failure and recurrence of the disease in women. (AM J OBSTET GYNECOL 1991;164:187-94.)

Many drug therapies have been used in the treatment of endometriosis with varying degrees of success. Estradiol and progesterone preparations were initially thought to cause regression of the disease by inducing a state of pseudopregnancy.[1] Danazol interacts with steroidogenic enzymes, receptors, and binding proteins, thereby creating a low-estrogen, high-androgen environment that is diametric to the growth of endometriotic tissue.[2,3] However, the use of exogenous steroids or danazol is associated with adverse side effects.[4] Therefore interest has been spurred in the development of a therapy to manage endometriosis that does not elicit the undesirable side effects of previous therapies.

Most recently, gonadotropin-releasing hormone (GnRH) analogs have been developed for the management of endometriosis.[4,5] GnRH analogs cause a reversible block of ovarian cyclicity. In turn, this hypogonadal state causes the regression of ectopic endometriotic tissue by inhibiting endometrial proliferation. GnRH agonists exert their antigonadal activity by down regulation of the GnRH receptor but may elicit stimulation of the disease if administered during the follicular phase of the menstrual cycle. The GnRH antagonists are competitive inhibitors of GnRH receptor binding and therefore do not cause the initial stimulation that may be found with the GnRH agonist.

The development of the long-acting GnRH antagonist antide has generated the promise of a potential endometriosis therapy that is free of the adverse effects of earlier drug therapies.[6] We have shown that a rapid regression of endometriosis occurs in the rat after treatment with antide.[7] However, prolonged GnRH analog therapy has been associated with hypogonadal side effects. To compensate for these effects, concurrent administration of exogenous steroids has been suggested.[5,8,9] However, the addition of steroids could contradict the beneficial effects of the GnRH analog in reduction of the endometriosis.

Regardless of the type of therapy, endometriosis recurs in a large proportion of patients on completion of treatment. The recurrence of endometriosis after cessation of therapy has been poorly studied because of the difficulty in performing repeated surgical observations in women. The lack of randomized, controlled clinical trials has also clouded the evaluation of medical treatments for endometriosis.[10] Therefore experimental endometriosis has been developed in animal models to evaluate the effects of drugs on endometriosis.[7,11-13] We designed these experiments to monitor the regrowth of the ectopic endometriotic tissue after complete suppression by antide and to evaluate the effects of exogenous steroid administration on antide-suppressed endometriosis in the rat.

Material and methods

Animals. Mature female Sprague-Dawley rats (250 gm; Harlan, Madison, Wis.) exhibiting regular 4-day estrous cycles were housed in environmentally controlled room with a 14-hour light, 10-hour dark cycle. Ovarian activity was indirectly measured daily at 7:00 AM in all rats by examination of vaginal cytology.[14] Rats were allowed a 2-week acclimation period in the vivarium before any procedure was performed. The rats were maintained in accordance with the National Institutes of Health "Guide for the Care and Use of Laboratory Animals" and the protocol for use of these rats was approved by the University of Kentucky.

Endometriosis was surgically induced in the rats by autotransplantation of uterine tissues as previously described by Vernon and Wilson.[15] Briefly, 3 mm squares of uterine tissue (implants) were obtained from the ablation of the distal third of the right uterine horn. The implants were autotransplanted to the arterial cascades of the intestinal mesentery with 4.0 nylon suture. After 6 weeks (for recuperation and development of endometriotic implants) experimentation began.

Experiment 1: Spontaneous recurrence of endometriotic implants after antide suppression. Rats with surgically induced endometriosis ($n = 56$) were subcutaneously injected with the GnRH antagonist antide [*N*-Acetyl-D-2-Naphthyl^1,D-4-ChloroPhe^2,D-3-Pyridyl^3, Nicotinoyl - Lys^5,D - Nicotinoyl - Lys^6,Isopropyl - Lys^8,D-Ala^{10}] with a regimen previously shown to suppress ovarian and hypothalamic activity.[14] Antide was designed and synthesized by Drs. K. Folkers and C. Y. Bowers and made available for research by the contraceptive development branch of the National Institute of Child Health and Human Development. Rats received antide (2 mg/kg) in oil or oil alone (vehicle control) at 12:00 noon on day 0 (proestrus) and days 3, 6, and 9. Rats were killed at 12:00 noon on days 0, 6, 12, 18, 24, 30, and 42 ($n = 4$ antide-treated and 4 vehicle-treated rats killed per day). At the time of death, rats were anesthetized with ether and sera were collected by means of cardiac puncture. Serum estradiol and progesterone levels were determined in our laboratory. All serum steroid concentrations were measured within the same assay. The intraasay coefficients of variation for the estrogen and progesterone assays were 9.3% and 6.4%, respectively. The endometriotic implants were photographed in situ, measured, and weighed. The data presented here are reported as length because the measurements of length, width, and volume yielded the same experimental results.

Experiment 2: Steroid-modulated regrowth of antide-suppressed endometriosis. A second group of rats with surgically induced endometriosis received antide ($n = 20$) or vehicle ($n = 4$) as described in exper-

iment 1. On day 9, 1 hour after the last antide treatment, these rats received a subcutaneous methylcellulose pellet that contained either estradiol (0.5 mg), progesterone (25 mg), estrogen plus progesterone, cholesterol control (Innovative Research of America, Rockville, M.D.), or no steroid pellet. The reproductively cyclic vehicle-treated rats did not receive steroids.

The rats in this experiment were killed at 12:00 noon on day 12, and therefore had received 72 hours of in vivo steroid exposure. Rats were killed and sera were collected as described above. All serum steroid concentrations were measured within the same radioimmunoassay. The coefficients of variation within the estrogen and progesterone assays were 7.3% and 3.2%, respectively. Some of the steroid concentrations for experiment 2 only, were presented elsewhere in tabular form.[14] The results of these steroid assays have been reproduced in figure form to illustrate the impact of exogenous steroid supplementation on antide-suppressed endometriosis.

Statistical analysis. Statistical analysis of the endometriotic implant size and serum steroid concentrations was performed with Statistical Analysis Systems general linear models computer program (SAS Institute, Cary, N.C.). When the F test from the analysis of variance indicated significance ($p < 0.01$), Duncan's multiple range test was used to evaluate differences in the least squares means of the endometriotic implant size and serum hormone concentrations.

Results

Animals. The rat has a 4-day estrous cycle that is easily monitored by changes in the vaginal cells.[14] The vaginal cells of the vehicle-treated animals were indicative of the characteristic 4-day estrous cycle of the rat for the duration of the project. However, as previously reported,[7, 14] antide elicited a rapid and profound period of anestrus (predominantly polymorphonuclear cells with few epithelial cells) that began on day 2. In experiment 1, anestrus continued until day 30, 21 days after the last antide injection. In experiment 2, the antide-treated rats also displayed a profound acyclic period beginning at day 2. However, at day 12 the vaginal cells of the rats treated with antide and estradiol or antide and estradiol plus progesterone displayed a mixture of rounded and cornified epithelium that is similar to the vaginal cells of a proestrus to estrus stage of the estrous cycle. The vaginal cells of the rats treated with antide and progesterone, antide and cholesterol, and antide and no steroid remained anestrus in appearance at day 12.

Experiment 1: Spontaneous recurrence of endometriotic implants after antide suppression. Six weeks after the initial surgery the mean length (± SEM) of the endometriotic implants had increased from the original size at autotransplantation of 3.00 mm to 5.58 ± 0.42 mm (day 0; Fig. 1). In the absence of antide, implant size was maintained throughout the experiment. However, antide began to suppress endometriotic implant size by day 6 (3.17 ± 0.42 mm). Significant suppression was observed ($p < 0.01$) on days 12, 18, and 24 (0.58 ± 0.42 mm, 0.50 ± 0.30 mm, and 2.71 ± 0.30 mm, respectively). By day 30 (4.71 ± 0.30 mm) and day 42 (6.00 ± 0.30 mm), implant size had returned to pretreatment values (Fig. 1).

The reduction in length of the endometriotic implant was coincident to the antide-induced suppression of the ovarian steroids. In the vehicle-treated rats, serum estradiol and progesterone concentrations were characteristic of the stage of their estrous cycle at the time of death[15] (Figs. 2 and 3). Antide suppressed serum estradiol on days 6, 12, and 18 as compared with the vehicle-treated rats ($p < 0.01$; Fig. 2). Serum progesterone concentrations of the antide-treated rats were also suppressed by day 6 but, unlike the estradiol concentrations, remained significantly suppressed for the duration of the study ($p < 0.01$; Fig. 3).

Experiment 2: Steroid-modulated regrowth of antide-suppressed endometriosis. In experiment 2, the length of the endometriotic implants from the vehicle-treated rats at death (day 12) was 5.88 ± 0.35 mm (mean ± SEM, Fig. 4). The implants of the rats that received antide without steroid stimulation were significantly suppressed (0.48 ± 0.30 mm; $p < 0.01$; Fig. 4) as compared with the vehicle-treated and steroid-treated rats. The administration of the exogenous steroids (day 9) caused a treatment-dependent response in the implants of the antide-treated rats. An increase in implant size was found in the rats treated with antide and estradiol (2.29 ± 0.47 mm), antide and progesterone (1.48 ± 0.33 mm), and antide and cholesterol (1.83 ± 0.37 mm) as compared with the rats that received antide alone ($p < 0.01$; Fig. 4). However, the size of the implants of the rats treated with antide and estradiol, antide and progesterone, and antide and cholesterol was not as great as that observed in the implants of the vehicle-treated rats or rats treated with antide and estradiol plus progesterone (4.63 ± 0.94 mm). The implants of the rats treated with antide and estradiol plus progesterone had reverted to a size similar to that observed in the vehicle-treated group (Fig. 4).

The serum estradiol and progesterone concentrations of the vehicle-treated rats were typical of the steroid concentrations observed in rats at 12:00 noon on the afternoon of proestrus[16] (Fig. 5). Both serum estradiol and progesterone were suppressed ($p < 0.01$) in the rats treated with antide and no steroid as com-

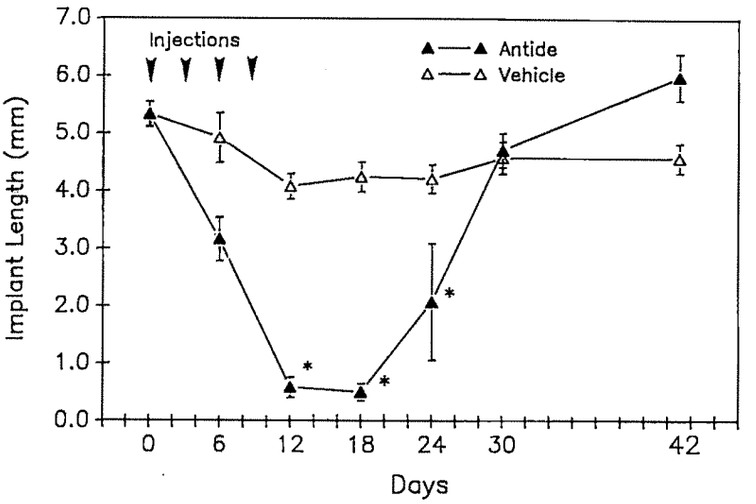

Fig. 1. Effect of antide on endometriotic implant length. Rats received four injections *(arrows)* of vehicle or antide over 9 days. Each point represents mean implant length ± SEM of six implants from each of four rats ($n = 24$ per point). Means marked with *asterisk* are statistically different from vehicle treatment ($p < 0.01$).

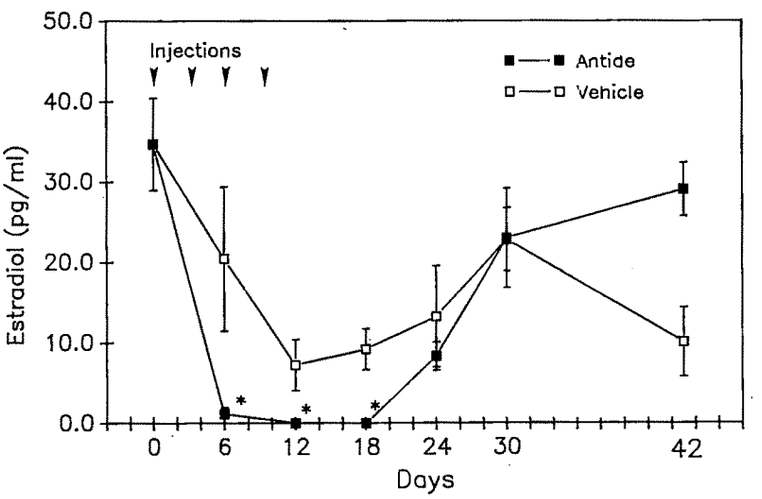

Fig. 2. Effect of antide on serum estradiol concentrations. Rats received four injections *(arrows)* of vehicle or antide over 9 days. Each point represents mean serum estradiol concentration ± SEM of four rats ($n = 4$ per point). Means marked with *asterisk* are statistically different from vehicle treatment ($p < 0.01$).

pared with all other treatments (Fig. 5). In the rats treated with antide and estradiol, serum estradiol concentrations were elevated ($p < 0.01$) as compared with those of rats that had not received estradiol treatment but not as great as those of the antide and estradiol plus progesterone. The serum progesterone concentrations of the rats treated with antide and estradiol were greater than those of the rats treated with antide and no steroid but similar to those of the vehicle-treated rats (Fig. 5). Serum estradiol remained suppressed ($p < 0.01$) in the rats treated with antide and progesterone. The serum progesterone concentrations of the rats treated with antide and progesterone were elevated ($p < 0.01$) as compared with those of the rats that did not receive progesterone treatment but similar to those of the rats treated with antide and estradiol plus progesterone (Fig. 5). Serum estradiol concentrations were greater ($p < 0.01$) in the rats treated with antide and estradiol plus progesterone than in all other groups. The serum progesterone concentrations of the rats treated with antide and estradiol plus progesterone were elevated ($p < 0.01$) as compared with those of the

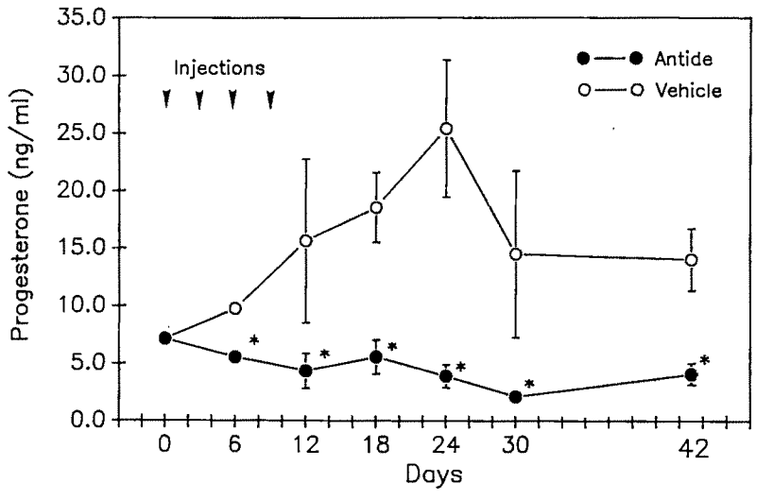

Fig. 3. Effect of antide on serum progesterone concentrations. Rats received four injections *(arrows)* of vehicle or antide over 9 days. Each point represents mean serum progesterone concentration ± SEM of four rats ($n = 4$ per point). Means marked with *asterisk* are statistically different from vehicle treatment ($p < 0.01$).

rats that had not received progesterone but similar to those of the rats treated with antide and progesterone (Fig. 5). In the rats treated with antide and cholesterol, serum estradiol was suppressed ($p < 0.01$) but serum progesterone was not different from the vehicle-treated rats (Fig. 5).

Comment

GnRH analogs have been used effectively in women for the treatment of endometrosis.[2, 4, 8] Although these analogs elicit regression of endometriotic tissue without the negative effects associated with earlier steroidal therapies, recurrence of the ectopic tissue occurs on cessation of the therapy. The mechanism of this recurrence is unclear. Previous research has not shown whether the growth of endometriosis observed after therapeutic suppression was renewed growth of the existing endometriosis or new disease. Part of the mystery that surrounds the mechanism of recurrent endometriosis in women stems from the ethical limitations in performing repeated laparoscopies. Therefore we have investigated the effects of the GnRH antagonist, antide, on endometriosis in the rat.

Antide, with its prolonged duration of action,[17] does have the potential to offer symptomatic relief by suppressing endometriosis as long as the drug exerts it antigonadal effects. We have previously shown that antide in the rat reduces the endometriotic implants to less than their original size at autotransplantation.[14] However, as we have shown here, this marked suppression of the endometriotic implants observed during antide therapy was spontaneously reversed within 3 weeks after the cessation of antide treatment or within 3 days after steroid replacement therapy. We did not observe a recurrence of the endometriotic implants while serum estrogen and progesterone concentrations were suppressed. Once the withdrawal from the suppressive effects of antide was complete and serum estradiol concentrations returned to physiologic levels, the regrowth of the endometriosis ensued. This resurgence of disease observed at the original sites of implantation in the rat suggests that recurrent endometriosis is a result of renewed growth rather than new disease. Therefore the potential transitory relief a patient may experience from the antide therapy would dissipate as regrowth of the endometriosis occurs. Others have shown a high clinical occurrence rate after GnRH agonist therapy was discontinued.[8] Hence, prolonged exposure to antide may be required to maintain remission of the endometriosis.

However, prolonged GnRH analog–induced hypogonadism has been associated with adverse side effects in women. These effects include hot flashes, headaches, vaginal dryness, dyspareunia, and a decrease in bone density that can ultimately lead to osteoporosis. To compensate for these side-effects, concurrent administration of exogenous steroids has been suggested. However, as the data presented here suggest, steroid add-back therapy could elicit regrowth of the GnRH analog–suppressed endometriosis.

Certain types of steroid replacement therapy abate the suppressive effects of GnRH analogs in the treatment of endometriosis.[18] We showed that steroid replacement markedly, but selectively, increased the endometriotic implant size in the antide-treated rats at a time (day 12) when the disease had not spontane-

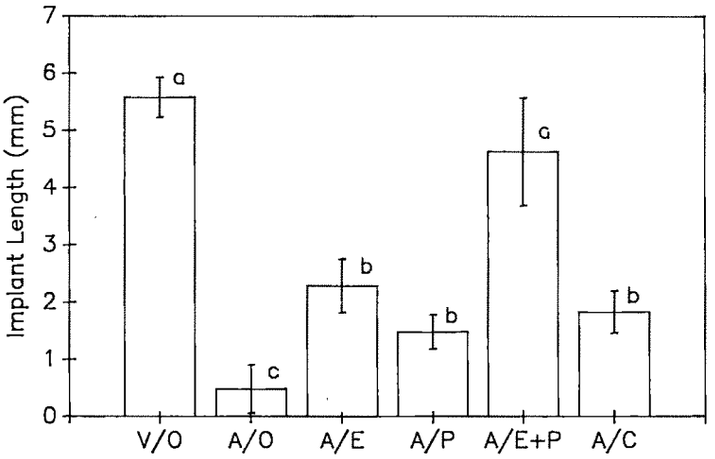

Fig. 4. Effect of steroid replacement therapy on endometriotic implant size of vehicle-treated and antide-suppressed rats. Vehicle treated rats *(V/O)* and antide only–treated rats *(A/O)* received no steroids. Remaining antide-treated rats received one of the four following steroid treatments: estrogen *(A/E)*, progesterone *(A/P)*, cholesterol *(A/C)*, or estrogen plus progesterone *(A/E + P)*. Means with different superscripts are significantly different from each other ($p < 0.01$; $n = 4$ per treatment group).

ously recurred in the rats that did not receive steroids. Estrogen plus progesterone replacement therapy elicited complete recurrence of endometriosis in antide-suppressed rats at 72 hours after the initiation of steroid replacement. A more subtle, yet significant, regrowth of the disease was observed when estradiol, progesterone, or cholesterol were administered individually. This differential response of the endometriotic implants to the steroid replacement therapies may have been a result of various mechanisms.

The substantial regrowth of the endometriotic implant observed when estradiol plus progesterone was given may be a reflection of the higher systemic concentrations of estradiol in this group. Although both the estradiol and estradiol-plus-progesterone groups received the same estradiol treatments, the serum estradiol concentrations were significantly greater in the latter group. These increased levels of serum estradiol might be attributable to peripherial aromatization of the exogenous progesterone to additional estrogenic compounds that elicited the enhanced regrowth. Although not studied here, further long-term exposure to estradiol could eventually cause a regrowth of the endometriosis similar to that observed with the estrogen-plus-progesterone treatment. In support of this idea, others have noted that long-term estrogen exposure will cause regrowth of endometriotic implant size in ovariectomized rats.[13] However, if peripheral aromatization of progesterone were occurring, one would expect to find increased estradiol concentrations in the progesterone-treated rats. No such increase in estradiol was found in the progesterone-treated rats.

Alternatively, one might speculate that the demonstrative rebound of the endometriotic implants in the estrogen plus progesterone–treated rats may be attributed to the presence of both estradiol and progesterone, which more closely mimicked a natural, in situ steroidal environment than either of the steroids alone. This idea is also supported by the fact that the estradiol-plus-progesterone regimen also induced changes in the vaginal cytology that were more indicative of a cyclic animal. However, the exact reason for the increased serum estradiol concentrations and hence the increased rate of growth of the endometriosis in the estradiol plus progesterone–treated rats cannot be discerned from these studies.

In the antide-treated animals that received progesterone (without estrogen), an increase in implant growth was also observed. The exogenous progesterone may have had estrogenic effects in vivo. Others have reported increased uterine weights in rats given progestins, indicating an estrogenic action.[19] However, no estradiol was found in the serum samples of the progesterone-treated rats, suggesting an alternate mechanism for stimulation of implant growth. The progesterone treatment might have increased the secretory capacity and elicited decidualization of the ectopic endometrium. These changes could be responsible for the accumulation of intracellular and extracellular fluids within the cystlike endometriotic implants thereby causing an increase in their size. On the other hand, prolonged subphysiologic levels of progesterone do not hinder the recurrence of the endometriosis after cessation of antide therapy. Spontaneous recurrence of the antide-suppressed endometriosis was observed (experiment 1) even though progesterone concentra-

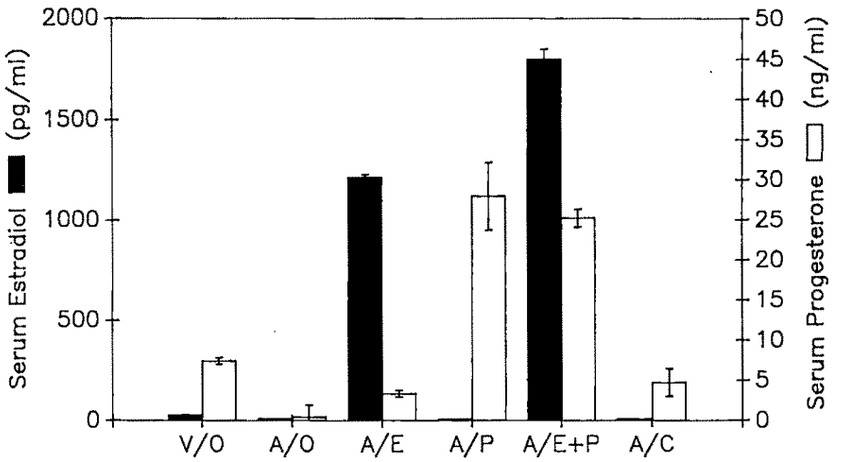

Fig. 5. Serum estrogen *(left axis)* and progesterone *(right axis)* concentrations after steroid replacement in antide-treated rats. Vehicle-treated rats *(V/O)* and antide only–treated rats *(A/O)* received no steroids. Remaining antide-treated rats received one of the four following steroid treatments: estrogen *(A/E)*, progesterone *(A/P)*, cholesterol *(A/C)*, or estrogen plus progesterone *(A/E + P)* ($n = 4$ per treatment group). Significant elevation ($p < 0.01$) in serum steroid concentration was observed in animals that received exogenous estradiol or progesterone *(A/E, A/P,* and *A/E + P)* relative to controls *(V/O* and *A/O)*.

tions remained diminished. These observations fit well with previous work that showed that the progesterone-induced stimulation of endometriosis with or without GnRH analog–therapy is dependent on both the type of progestin used and the regimen by which it is administered.[8-9, 18]

The regrowth of the endometriotic tissue observed in the antide-treated rats after the administration of cholesterol was unexpected. The serum progesterone of the cholesterol-treated rats was similar to the vehicle-treated rats, indicating that the cholesterol could have been metabolized to progesterone in the adrenal glands or ovaries. The administration of antide may have altered the cholesterol or steroid metabolism of these rats. Another explanation for the increased serum progesterone of this group was that the cholesterol pellet was contaminated with progesterone. However, analysis of these pellets in our laboratory showed that this was not the case. Although unlikely, the possibility exists that the methylcellulose itself may have been responsible for the effects seen in the cholesterol group. The mechanism of endometriotic implant regrowth after cholesterol treatment requires further investigation.

The benefits of GnRH analog–treatment for endometriosis-associated infertility remain to be confirmed. Use of the GnRH agonist, nafarelin, has indicated a potential for increased fecundity rates similar to those seen in endometriosis patients treated by conservative surgery or danazol therapy.[20] However, at doses sufficient to suppress endometriosis, we previously showed that the antagonistic analog antide generates follicular atresia and infertility in the rat.[14] It is obvious that care must be taken when results are extrapolated across species, but these observations of spontaneous recurrence of endometriosis along with the previously reported antide-induced infertility justify further investigation into the mechanisms of action of this GnRH antagonist on both endometriosis and folliculogenesis.

In summary, although antide elicits a marked suppression of endometriosis in the rat, regrowth of the disease ensues with cessation of therapy. Furthermore, steroid replacement therapy stimulates the rapid recurrence of the endometriotic implant growth. If also present in women, this persistence of endometriosis may partially explain treatment failure and recurrence of the disease after hormone therapies.

Diastolic circulatory dynamics in the presence of elevated placental resistance and retrograde diastolic flow in the umbilical artery: A Doppler echographic study in lambs

Jean-Claude Fouron, MD, Georges Teyssier, MD, Enrique Maroto, MD, Manon Lessard, RT, and Gerald Marquette, MD

Montreal, Quebec, Canada

To evaluate the effects of elevated placental resistance on the diastolic blood flow in the main arteries of the fetus, placental resistance was mechanically increased in six exteriorized lambs. A string was inserted into the exposed section of the umbilical cord and placed around the veins isolating them from the arteries. Doppler flow velocities waveforms were measured by placing a lightweight acoustic bag on the umbilical cord. Placental resistance was increased by tightening the string until retrograde diastolic flow was observed in the umbilical artery. All measurements were obtained within 10 minutes. Heart rate, Po_2, Pco_2, and pH before umbilical vein compression were 177 ± 24 beats/min, 16.4 ± 1.8 mm Hg, 42.5 ± 4 mm Hg, and 7.3 ± 0.05, respectively, and 112 ± 38 beats/min, 5.9 ± 1.5 mm Hg, 56.6 ± 7.0 mm Hg, and 7.2 ± 0.05, respectively, after umbilical vein compression. The patterns of diastolic flow observed after compression were descending aorta, retrograde; aortic arch, retrograde; ascending aorta, bidirectional; cephalic aorta, forward, which were quite different from their respective baseline patterns. It is concluded that the appearance of reverse diastolic flow in the umbilical artery indicates that (1) the lowest vascular resistance in the fetal circulatory network is no longer at the placental but at the cerebral level, and (2) preplacental blood with low oxygen content from the descending aorta and pulmonary artery is being shifted toward the brain. (Am J Obstet Gynecol 1991;164:195-203.)

Key words: Fetus, Doppler ultrasonography, umbilical circulation

There is convincing evidence that shows that an increase in placental resistance is associated with a decrease and sometimes a complete disappearance of the diastolic forward flow normally observed in the umbilical artery.[1, 2] In severe cases, a reversal of this diastolic flow has even been observed.[3] Whereas the absence of diastolic flow can be explained by an increase in placental vascular impedance, no satisfactory explanation has been given for the retrograde flow documented in very ill fetuses. A rebound phenomenon against a high resistance can hardly explain this low velocity flow that frequently occupies the entire diastole and is recorded not only in the umbilical circulation but also in the descending aorta.[4, 5] Whereas in systole the progression of blood flow is primarily ensured by the driving force of the cardiac pump, in diastole the main factor left to influence the distribution of the blood into the various vessels is the peripheral resistance. Therefore this Doppler echographic study was planned with the hypothesis that a more defined assessment of the orientation of the blood stream in the main fetal arteries during diastole could provide some insight on the changes in the peripheral resistances and circulatory dynamics resulting in umbilical diastolic retrograde flow.

Material and methods

This project was approved by the Ethical Committee for the care and use of animals of our institution. Six fetal lambs were used in this experiment. The gestational age of each lamb was >140 days. The ewes were anesthetized with alternating intravenous injections of ketamine hydrochloride (3 mg/kg) and sodium pentobarbital (Nembutal) (2 mg/kg) every 20 to 40 minutes. The uterine wall was first marsupialized to the border of the surgical abdominal wound. This precautionary measure ensured that the uterus remained within the abdominal cavity throughout the experiment. Great care was taken to prevent torsion or undue traction of the uterine horn, thereby ensuring an adequate blood flow through the uterine artery. The hind limb of the fetus was first exteriorized allowing can-

nulation of one of the femoral arteries for blood gas analysis and arterial pressure recordings in the descending aorta. This was followed by complete exteriorization of the fetus, which was required for the Doppler echographic investigation. The head of the fetus was put into a rubber bag containing warm saline solution to prevent breathing. The animal was kept very close to the laparotomy incision, keeping most of the umbilical cord inside the uterine cavity to minimize tension. Only a few centimeters of the umbilical cord were used for the flow velocity measurements. This section was regularly humidified with warm saline solution. Fetal temperature was kept constant between 38.5 and 39.5° C with the help of a heating lamp.

Ultrasonographic evaluations were obtained with a Sonos-100 HP echocardiograph equipped with real-time and pulsed Doppler echocardiographic capabilities. Doppler investigation was guided by two-dimensional imaging of the vascular structures with a 5 MHz mechanical transducer. The Doppler flow velocity studies were based on determinations made through the left subxiphoid approach. From this approach the ascending aorta, the bifurcation between the cephalic branch and the aortic arch, and the descending aorta could be well visualized (Fig. 1). Doppler flow velocity waveforms in the umbilical artery were recorded with the help of a standoff acoustic bag. Great care was taken to avoid any compression of the cord, which was surrounded by its natural Wharton jelly. The acoustic bag was made in our laboratory by filling one finger of a fine rubber glove with warm acoustic jelly and gently placing it over the umbilical cord. The absence of compression or vessel reaction was reflected by the presence of a significant diastolic flow on the Doppler flow velocity waveform.

Arterial pressure was constantly recorded during this procedure with a Cambridge recorder. Arterial pH, Po_2, and Pco_2 were analyzed on samples of 0.8 ml of blood with a blood gas analyzer from Instrument Laboratory Equipments.

Experimental protocol. The animals were considered to be in a basal state when two consecutive blood samples and pressure recordings taken 5 minutes apart showed blood gas values, arterial pressure, and heart rate as being stable and within normal physiological limits. Flow velocity waveforms in the umbilical artery were then recorded (Fig. 2, *A*), followed by recordings in the ascending aorta, cephalic aorta, aortic arch, and descending aorta. The recordings were obtained as quickly as possible to achieve a complete assessment of the diastolic patterns within 10 minutes. To ensure that the measurements were recorded during the same acute condition (similar degree of placental resistance), umbilical artery blood flow velocity waveforms were recorded immediately after each series of Doppler interrogations and compared with the results obtained before the commencement of the scannings.

To create high placental resistance, a small umbilical

string was gently inserted through the Wharton jelly directly between the arteries and the veins thereby separating them from each other. While the baseline data were collected the string was loosely tied, not exerting any pressure, around the veins and fixed with a pair of small hemostatic forceps. After the basal measurements were recorded, the umbilical veins were mechanically compressed by tightening the string. Doppler flow velocity monitoring was continuous throughout the basal and compression conditions. Because the aim of the study was to assess the peripheral vascular resistance during reverse umbilical flow, the procedure was stopped immediately when retrograde diastolic flow was detected in the umbilical artery (Fig. 2, *B*). Flow velocity measurements were then carried out on the same vascular sites described in the basal state. Blood samples were withdrawn for blood gas analysis toward the end of the Doppler recordings.

Data analysis. The diastolic flow patterns in each of the vascular sites evaluated were classified according to the direction of the blood stream. Thus the diastolic flow could be described as forward when in the same

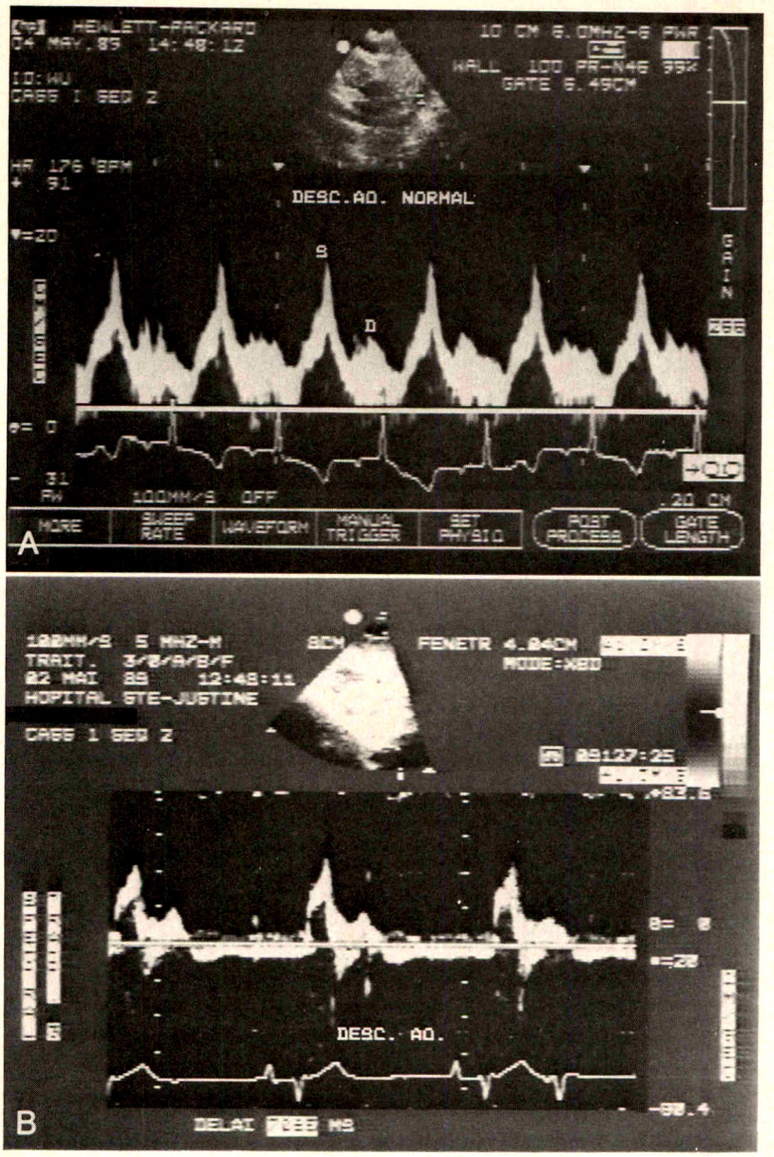

Fig. 3. Velocimetry in the descending aorta. **A,** At basal condition, forward flow is recorded in diastole. **B,** During umbilical vein compression, diastolic reverse flow is observed.

direction as systolic flow during the entire (forward total) or part (forward partial) of diastole; retrograde when in the opposite direction compared with systolic flow during the entire (retrograde total) or part (retrograde partial) of diastole; absent when no Doppler signals could be recorded in diastole; and bidirectional when Doppler signals could be recorded alternating between forward and retrograde during the same diastolic period.

Pulsatility index was calculated in the umbilical artery as described by Gosling.[6] Blood gas values, arterial pressures, and pulsatility indexes obtained during normal and increased placental resistance were compared with the paired Student *t* test.

Results

Basal condition (low placental resistance). The blood gas values, arterial pressures, heart rate, and pulsatility indexes are given in Table I. All six animals had the same patterns of diastolic blood flow. They were as follows: umbilical artery, forward total (Fig. 2, *A*); descending aorta; forward total (Fig. 3, *A*); aortic arch,

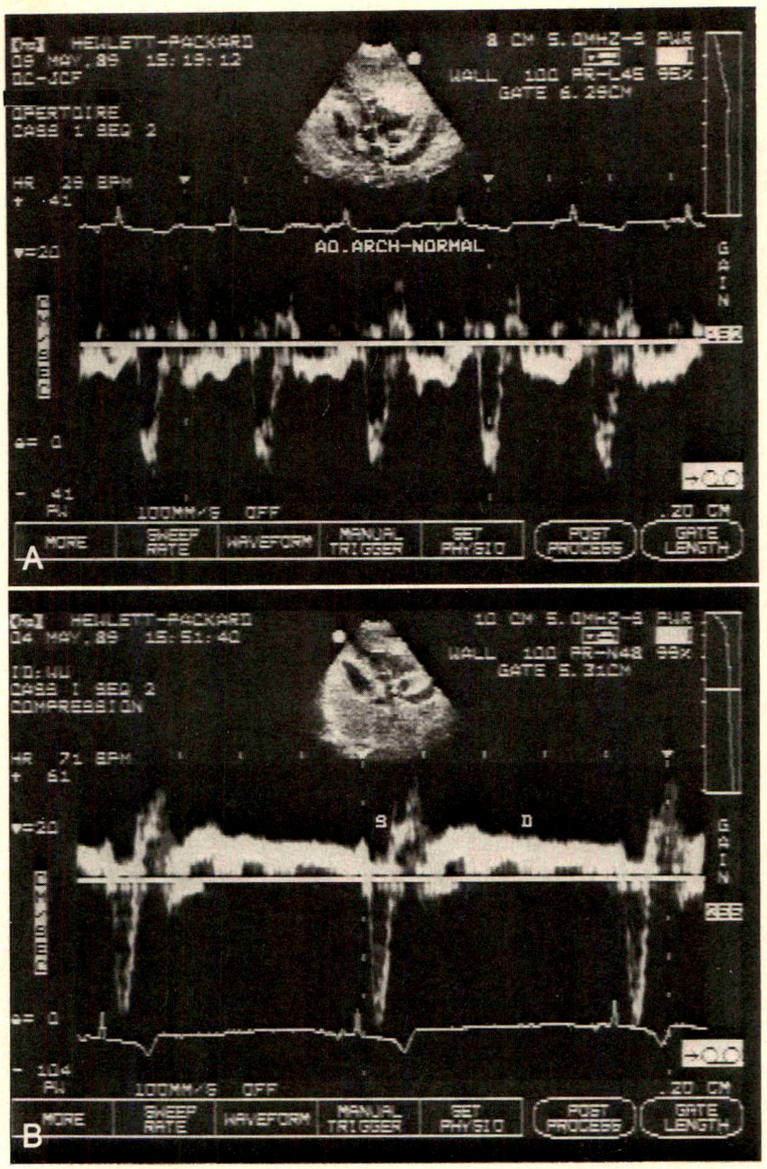

Fig. 4. Velocimetry in aortic arc. **A,** At basal condition, forward diastolic flow. **B,** Retrograde flow during umbilical vein compression.

forward total (Fig. 4, *A*); ascending aorta, bidirectional (Fig. 5, *A*); cephalic aorta, bidirectional (Fig. 6, *A*).

Umbilical vein compression (high placental resistance). Temperature, arterial pressure, and blood gas values were monitored at very close intervals. Table I shows the blood gas values and arterial pressures in the descending aorta, along with heart rate and umbilical artery pulsatility indexes obtained during umbilical vein compression. A marked drop of P_{O_2} and a moderate rise of P_{CO_2} were observed when compared with the basal state ($p < 0.01$). The pH did not change significantly. Whereas arterial pressures increased above baseline values immediately after umbilical vein compression, no statistical significance was reached. As noted in Table I, the pulsatility index reached an average of 1.82 in the umbilical artery after compression, which was statistically significant from the basal state value of 0.58. A marked bradycardia was observed during compression, and this difference between the normal (basal state) and the abnormal (during mechanical compression of the umbilical veins) heart rate values was found to be statistically significant. The patterns of diastolic flows were the same for all six animals: umbilical artery, retrograde total (Fig. 2, *B*); descending

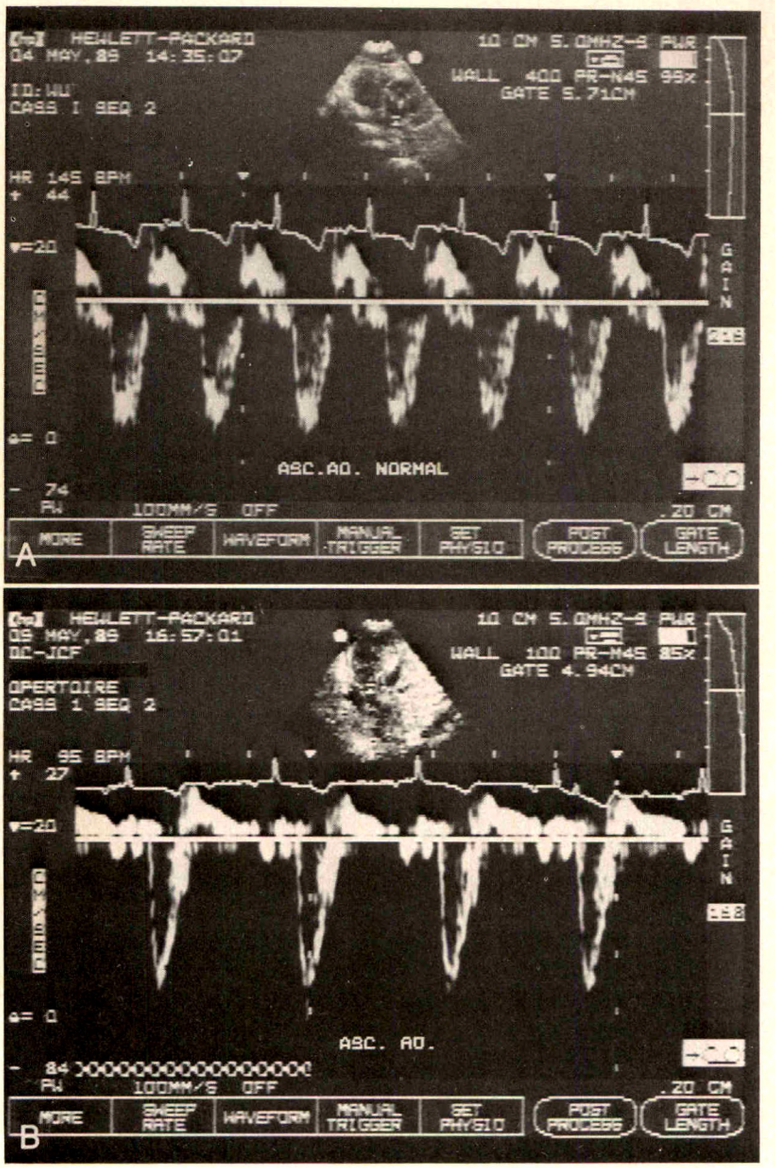

Fig. 5. Velocimetry in ascending aorta shows bidirectional diastolic flow both before **(A)** and during umbilical vein compression **(B).**

aorta, retrograde total (Fig. 3, *B*); aortic arch, retrograde total (Fig. 4, *B*); ascending aorta, bidirectional (Fig. 5, *B*); cephalic aorta, forward total (Fig. 6, *B*). Thus the cephalic aorta was the only main artery where forward flow was recorded during the entire diastole.

Comment

The application of the Doppler echographic technique to the assessment of blood flow velocities in the fetus is hampered by factors such as difficulties in obtaining the proper angle of insonation, a moving target, the size of the vessels that require a very small sample volume, and the distance between the transducer and the blood vessels. The protocol of our investigation added another element to these limiting factors by requiring a Doppler flow velocity sampling in five different sites along the systemic circulation during a relatively short period of time (<10 minutes). Preliminary trials confirmed that satisfactory data could not be collected on a chronic preparation with the transabdominal ultrasonograph approach because it was never possible to obtain a proper recording in all five vascular sites within the relatively short time period required by the protocol. Therefore we elected to obtain the desired information on an exteriorized fetus. Stress and fetal deterioration associated with this approach have been

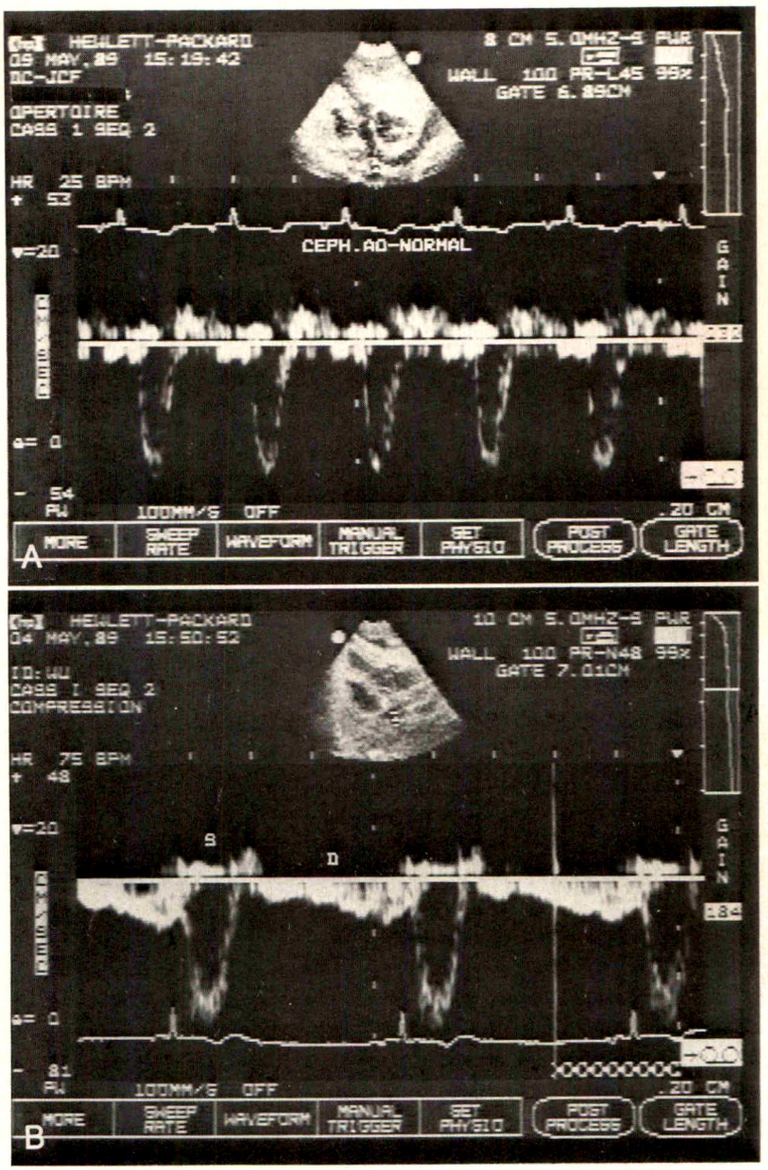

Fig. 6. Blood flow velocity waveforms in cephalic aorta. **A,** In diastole forward and retrograde flows are normally observed. **B,** With elevated placental resistance, only forward flow is recorded during entire diastole.

well described.[7] To minimize these drawbacks the duration of the entire experiment was kept to a minimum, and great care was taken to keep the uterus and the umbilical cord in the maternal abdominal cavity throughout the experiment. Previous attempts by other investigators with the same approach have given satisfactory results.[8]

Diastolic events in a given circulatory bed are greatly influenced by the status of the peripheral vascular resistance. In a normal fetus the peripheral circulation is characterized by two specific elements: a high pulmonary and a low placental vascular resistance. In fact, the vascular network with the lowest resistance in the entire circulatory system is at the level of the placental vascular bed. Doppler flow velocity recordings have confirmed this fundamental aspect of fetal circulation by documenting the presence of a significant forward diastolic flow in the umbilical artery. The low placental resistance affects the direction of blood flow during diastole in the descending aorta and as far as the aortic arch. Consequently, any change in placental vascular resistance is bound to profoundly disturb the normal dynamics of the fetal circulation. Therefore a progressive increase in placental resistance should cause a

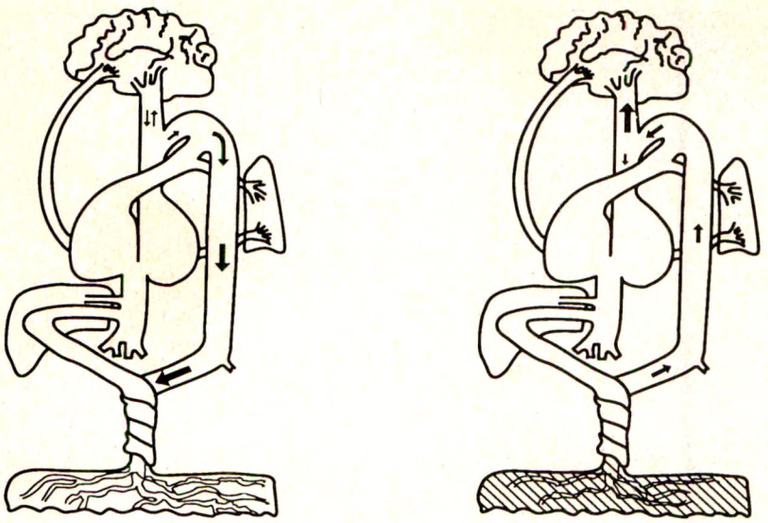

Fig. 7. Schematic representation of fetal diastolic flow distribution in presence of normal *(left)* and increased *(right)* placental vascular resistance.

Table I. Blood gas values and pressures in the descending aorta, and pulsatility indexes of the umbilical artery during normal and mechanically produced abnormal placental resistance

*Significant difference from normal values ($p < 0.05$).

corresponding decrease of the forward flow in the aorta and the aortic arch where complete disappearance of any significant blood flow in diastole can be observed. However, any further increase in placental resistance will then create an altered hemodynamic state in which the lowest vascular resistance is no longer at the placental level, but rather at the cerebral level. Indeed, in the presence of hypoxemia, as a result of the decrease in placental blood flow, vasodilation of the cerebral vessels will occur. The rise in Pco_2, a consequence of placental insufficiency, also promotes further cerebral vasodilation. When diastolic retrograde flow is observed in the umbilical artery, this indicates that during diastole the blood is actually flowing from the umbilical artery, the descending aorta, and the aortic arch toward a lower resistance—the vascular channels of the cerebral circulation. A schematic representation of this altered hemodynamic state is illustrated in Fig. 7. Analogous situations are known to occur in extrauterine life in cases with cerebral arteriovenous fistula.[9] Reverse diastolic flow from the descending aorta to the pulmonary artery has also been well documented in infants with patent ductus arteriosus and left-to-right shunting.[10]

Bradycardia was observed in all fetuses during umbilical vein compression. This was most likely related to baroreceptor activation by the arterial pressure rise in response to the change in systemic vascular resistance. Whereas bradycardia is known to increase the pulsatility index, it usually does not do so to the point of complete disappearance of diastolic forward flow, and it most certainly does not produce retrograde flow. This is exemplified in fetuses with complete arteriovenous block and marked bradycardia in which diastolic reverse flow in the umbilical artery was never observed in our experience. We do not think that bradycardia alone can explain the results observed in this study. Therefore for retrograde flow to occur in the umbilical artery another vascular bed somewhere in the circulatory system must have a lower impedance than the placental vascular system.

In the fetus a reverse diastolic flow from the descending aorta and umbilical artery toward the cerebral circulation would have disastrous effects on tissular oxygenation. Blood going in retrograde fashion through the aortic arch is then made of preplacental red cells, low in oxygen content, deviated from their normal route, the placental circulation. In these circumstances

the so-called "brain saving reflex" characterized by a cerebral vasodilation in response to hypoxemia[11, 12] could actually be detrimental to the brain. Indeed, vasodilation of the cerebral vessels should hasten the inversion of the relationship between placental and cerebral resistances. In our anesthetized animals this factor was probably not much of a determinant because pentobarbital has a depressing effect on the contractile response of the cerebral arteries.[13] However, this does not change the actual mechanism by which diastolic retrograde flow occurs. It can be speculated that without induction of anesthesia, as is most often the case in clinics, hypoxic active cerebral vasodilation will occur and reverse diastolic flow will be observed at a lower level of placental vascular resistance than the maximal resistance created during this study.

These data were collected from acute experiments on anesthetized animals. Further investigations should be carried out to evaluate their clinical implications. If confirmed in human beings, the hemodynamic events reported in this experimental study would certainly explain why the appearance of reverse diastolic flow in the umbilical artery and the descending aorta is considered a sign of impending fetal death.[14]

We are thankful to Marie Therese Rabeau for her technical assistance and to Susan Pamela Drblik for her help and advice in editing this manuscript.

Forskolin and methotrexate induce an intermediate trophoblast phenotype in cultured human choriocarcinoma cells

Robert N. Taylor, MD, PhD,[a] Erin D. Newman,[a] and Shiuan Chen, PhD[b]

San Francisco and Duarte, California

The human placenta and its associated membranes are vital to the maintenance, nutrition, and protection of the developing fetus. During placental development some cytotrophoblasts give rise to the chorionic membrane whereas others fuse to form a differentiated syncytium of cells that are responsible for placental protein and steroid hormone production. The mechanisms involved in the differentiation of the trophoblasts are unknown; however, an intermediate stage with a characteristic phenotype has been documented in vivo. We have observed that chemically dissimilar xenobiotic agents induced BeWo choriocarcinoma cells to change their usual cytotrophoblastic phenotype and acquire morphologic and functional characteristics typical of intermediate trophoblast. Incubation of BeWo cell cultures in the presence of 1 μmol/L methotrexate for 48 hours stimulated human chorionic gonadotropin secretion (2.3-fold) and aromatase activity (4.9-fold). Morphologic findings associated with these hormonal changes, including increased nuclear size and cytoplasmic expansion, were also observed. With the use of a computer-interfaced image analyzer, planimetric morphometry of the nuclear area of the cells revealed a 1.8-fold increase after incubation with methotrexate. The effect of forskolin, a direct activator of adenylyl cyclase, was also evaluated by means of this model of cytotrophoblast differentiation. The addition of 10 μmol/L forskolin to BeWo cultures also resulted in dramatic changes in trophoblast cell phenotype. Increases in human chorionic gonadotropin synthesis (7.3-fold), aromatase activity (13.5-fold), and nuclear area (3.0-fold) were induced over those of untreated cells. In addition, increases in [^{3}H]thymidine incorporation (1.7-fold) were afforded by both treatments. These results suggest that biochemical and cytologic changes associated with human trophoblast differentiation can be induced in vitro via activation of the adenylyl cyclase pathway by forskolin and through unknown and apparently independent signals by methotrexate. (Am J Obstet Gynecol 1991;164:204-10.)

Key words: Intermediate trophoblast differentiation, cyclic adenosine monophosphate, methotrexate

The early development of the human placenta is initiated by the differentiation of trophectoderm cells at the periphery of the preimplantation blastocyst. During implantation, undifferentiated mononuclear cytotrophoblast cells derived from the trophectoderm proliferate to form an invasive shell of tissue, which anchors the pregnancy to the uterine stroma. During the process of placental development, cytotrophoblasts differentiate and fuse, forming a syncytium of trophoblast that covers the placental villi.[1, 2] The process of trophoblast differentiation appears to involve a morphologic intermediate or transitional cell, which is the immediate precursor of syncytial trophoblast and has distinctive biochemical and cytologic characteristics.[2, 3] Syncytiotrophoblast is the primary site of synthesis and secretion of the major protein and steroid hormones of the placenta.[4] The reprogramming of cytotrophoblast cells with proliferative and invasive activities to establish a terminally differentiated syncytium with endocrine function is accomplished via unknown mediators. It is known, however, that cyclic adenosine monophosphate (cAMP)–mediated processes are involved in the promotion of human chorionic gonadotropin (hCG) and estrogen secretion in normal and malignant trophoblast cells.[5-8]

In this report we have examined a model of trophoblast differentiation using a human cell line (BeWo) derived from a choriocarcinoma.[9] Friedman and Skehan[10] were the first to show that BeWo cells with cytotrophoblast-like features under basal conditions could be induced to acquire syncytiotrophoblastic ultrastructure and behavior when cultured in the presence of 1 μmol/L methotrexate. The pathways by

which this antimetabolite effects such a transformation are unknown. Using this model we have demonstrated that two dissimilar xenobiotic agents, methotrexate and forskolin, act at a pretranslation level of regulation to induce an intermediate trophoblast phenotype in vitro.

Material and methods

Cell culture. BeWo choriocarcinoma cells (A63643) were obtained from the University of California, San Francisco, Cell Culture Facility and were maintained in RPMI 1640 media supplemented with 10% fetal calf serum as described by Friedman and Skehan.[10] Cells were plated at a density of 15,000 cells per well in 24-well Falcon dishes (Becton Dickinson, Lincoln Park, N.J.) and cultured for 2 days until each well was ~50% confluent. The media were aspirated and replaced with serum-free media containing forskolin, methotrexate, or no additive for 48 hours. Serum-free medium was prepared with RPMI 1640 supplemented with 20 mmol/L HEPES buffer (N-[2-hydroxyethyl]piperazine-N'[2-ethanesulfonic acid]), insulin (1 μg/ml), transferrin (5 μg/ml), bovine serum albumin (500 μg/ml), and penicillin-streptomycin (100 U/ml) obtained from Sigma (St. Louis). Unless indicated otherwise, the concentrations of forskolin and methotrexate were 10 and 1 μmol/L, respectively, which consistently gave near maximal responses of the morphologic and biochemical features described. Dibutyryl cAMP was used at a concentration of 1 mmol/L. At the end of each experiment, cells were trypsinized from representative wells and their numbers determined with a hemacytometer.

Cytologic analysis. Cells grown on plastic coverslips were fixed with 4% paraformaldehyde in phosphate-buffered saline solution (pH 7.4), stained with toluidine blue, and examined by light microscopy. Photomicroscopy was performed on a Leitz Ortholux II microscope equipped with a Vario Orthomat camera (E. Leitz, Rockleigh, N.J.). Planimetric morphometry was used to determine nuclear area with a Zeiss interactive digital analysis system (Zidas; Carl Zeiss, Thornwood, N.Y.). The nuclear areas of 150 cells were quantified.

[^{3}H]Thymidine incorporation. Cells grown for 48 hours in serum-free media in the absence (control) or presence of forskolin or methotrexate were pulsed for the last 4 hours of culture with 1 μCi/ml [^{3}H]thymidine (New England Nuclear, Boston). The incorporation of labeled nucleotide into 10% trichloroacetic acid–precipitable counts was determined by liquid-scintillation counting as described.[11]

hCG secretion. The secretion of hCG into the media of each culture was quantified with a specific double-antibody radioimmunoassay for the β-subunit described previously.[12] The sensitivity of this assay was 2 mIU/ml.

Northern analysis. BeWo cell ribonucleic acid (RNA) was extracted with guanidine thiocyanate (Fluka Chemie, Buchs, Switzerland) and purified over cesium chloride gradients.[13] hCG-β and aromatase messenger RNA (mRNA) accumulation in cultured BeWo cells was determined by electrophoresis of 10 μg aliquots of total cellular RNA after denaturation with glyoxal and dimethylsulfoxide as described by Thomas.[14] After electrophoresis, the 1% agarose gels were assessed by ultraviolet shadowing against a silica gel plate to ascertain that each lane contained equal amounts of ribosomal RNA. The RNA was transferred to nitrocellulose and hybridized with complementary DNA (cDNA) probes labeled with [α-^{32}P]2′-deoxycytidine 5′-triphosphate (~3000 Ci/mmol; New England Nuclear) and a random-primer kit (Boehringer-Mannheim, Indianapolis). The hCG-β cDNA (0.6kb)[15] was generously provided by Drs. Karen Talmadge and John Fiddes (California Biotechnology, Inc., Mountainview, Calif.). The human aromatase cDNA (2.4 kb) was described previously.[16]

Aromatase activity. The capacity of cells to synthesize estrogens was assessed by quantifying the enzymatic conversion of saturating concentrations of [1β, 2β-^{3}H]androstenedione to tritiated water and estrogen.[17] Briefly, BeWo cells exposed to control media or media containing forskolin (10 μmol/L) or methotrexate (1 μmol/L) for 48 hours were rinsed twice with phosphate-buffered saline solution and then incubated in 1 ml RPMI 1640 medium containing 1 μmol/L [1β,2β-^{3}H]androstenedione (diluted to a final specific activity of 5 Ci/mmol; New England Nuclear) for one hour at 37° C. The plates were transferred to an ice bath, the media were removed and extracted with chloroform, and the aqueous phases were chromatographed over minicolumns of charcoal and Celite and analyzed for tritium by scintillation counting. The cells were trypsinized from their respective wells and counted with a hemacytometer to normalize aromatase activities.

cAMP content. After 48 hours of incubation in control, forskolin-containing, or methotrexate-containing media, BeWo cells were solubilized and extracted with 0.1N hydrochloric acid. Cellular cAMP was acetylated by incubation in the presence of triethylamine/acetic anhydride, and its content was determined with a specific radioimmunoassay for cAMP.[18] Rabbit antiserum to cAMP was obtained from Chemicon (El Segundo, Calif.).

Statistical analyses. Data are presented as the mean ± SEM of replicate experiments. The treatment and control groups were compared by use of two-tailed analysis of variance. Where analysis of variance suggested that the treated cells had elevated phenotypic markers, specific treatments were compared against the

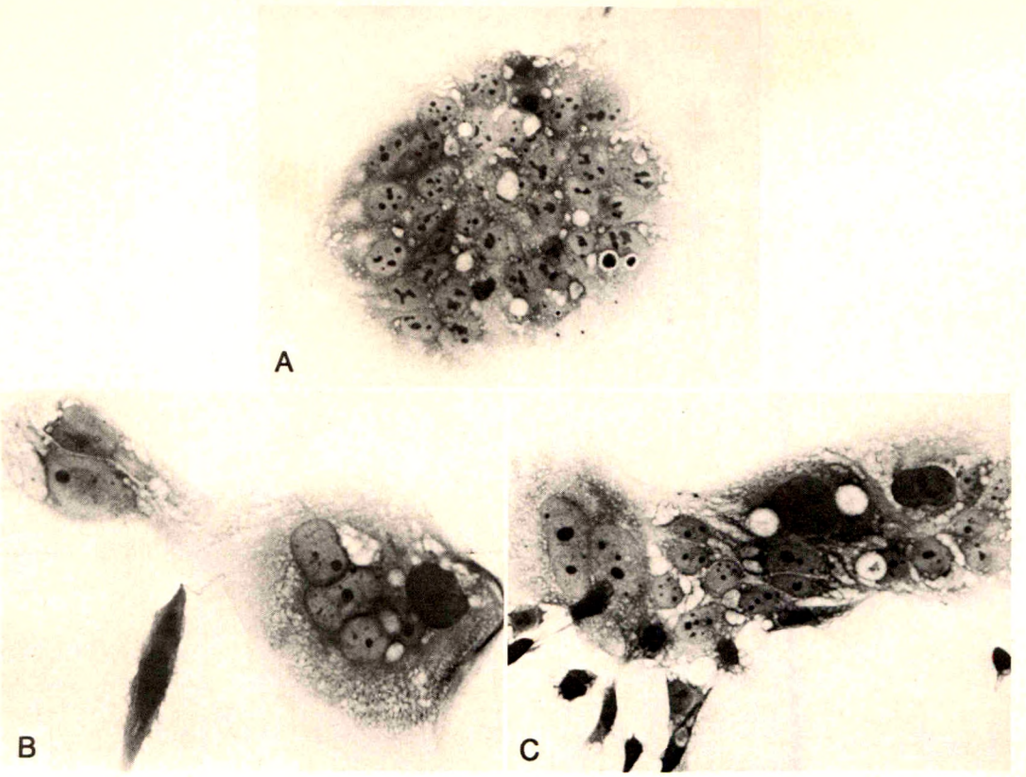

Fig. 1. Cytologic changes induced in BeWo cells. **A,** Control cells cultured in serum-free media for 48 hours contained uniform, small nuclei. **B,** Forskolin (10 μmol/L) exposure for 48 hours was associated with cytoplasmic and nuclear enlargement with prominence of nucleoli. **C,** Phenotypic changes similar to those seen in **B** were also noted after 48 hours of incubation with 1 μmol/L methotrexate. control group with Fisher's least significant difference method (one-tailed test) and were considered significant at $p < 0.05$.

Results

Cytologic-nuclear analyses. Exposure of monolayers of BeWo cells to culture media containing forskolin or methotrexate for 48 hours resulted in reproducible morphologic changes similar to those that had been previously described for the latter agent.[10, 19] In serum-free medium, relative to untreated control cells (Fig. 1, *A*), both cytoplasmic and nuclear compartments of the cells were noted to enlarge after 48 hours of incubation with either forskolin or methotrexate (Fig. 1, *B* and *C*, respectively.) In addition, the nuclei of treated cells developed lobations and prominent nucleoli. Planimetric morphometry of the nuclear areas of fixed BeWo cells revealed 3.0- and 1.8-fold increases after exposure to forskolin and methotrexate, respectively, which differed significantly from the mean area of control nuclei ($p < 0.05$). These increases in nuclear size were associated with increases in DNA synthesis (1.7- and 1.8-fold, respectively) as determined by [^{3}H]thymidine incorporation. However, despite increases in DNA synthesis, the treatments did not appear to stimulate cell division relative to the control condition (Table I).

Hormone activities. To assess the endocrine activities of these cells, production of the quintessential protein and steroid hormones of human placental origin, hCG and estrogen, was quantified. Radioimmunoassays of conditioned media demonstrated that hCG-β secretion was increased over basal concentrations by forskolin (7.3-fold) and methotrexate (2.3-fold) (Table II). Dose-response relationships of hCG-β secretion to increasing concentrations of forskolin revealed that 10 μmol/L was optimal in promoting this differentiated response. It was also noted that the stimulation of [^{3}H]thymidine incorporation appeared to be coupled to the induction of hCG-β secretion by forskolin, in a parallel dose-dependent manner (Fig. 2).

Similarly, activity of the rate-limiting enzyme system responsible for placental estrogen production, aromatase, was augmented in the presence of the two agents. Methotrexate (1 μmol/L) induced a 4.9-fold stimulation of basal BeWo aromatase activity, whereas forskolin (10 μmol/L) increased the conversion of an-

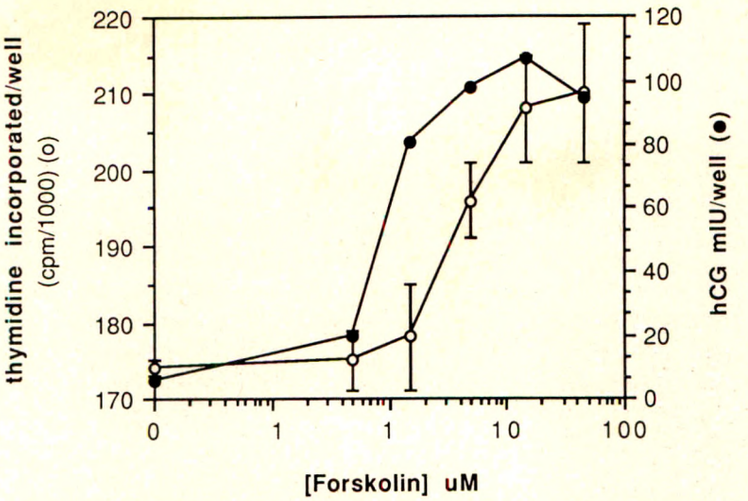

Fig. 2. Correlation of [^{3}H]thymidine incorporation and hCG-β secretion in BeWo cells exposed to forskolin. Increasing concentrations of forskolin were added to cultures of BeWo cells grown in 24-well dishes. Cellular incorporation of [^{3}H]thymidine *(open symbols)* and hCG-β secretion into the culture media *(closed symbols)* were determined after 48 hours as described in material and methods. The *error bars* represent the SEM of triplicate determinations.

Table I. Effects of treatment of cytologic-nuclear changes

Treatment	*Cell number ($\times 10^5$)*	*Nuclear area (μm^2)*	*[^{3}H]thymidine incorporation (cpm/cell)*
Control	2.0 ± 0.5	300 ± 20	0.9 ± 0.2
10 μmol/L Forskolin	2.9 ± 0.3	904 ± 66*	1.5 ± 0.1
1 μmol/L Methotrexate	2.1 ± 0.2	539 ± 46*	1.6 ± 0.3*
Analysis of variance	NS	$p < 0.05$	$p < 0.05$

*Values are significantly greater than control by Fisher's multiple comparison method ($p < 0.05$).

Table II. Effects of treatment on endocrine changes

Treatment	*hCG-β secretion (mIU/ml/10^5 cells)*	*Aromatase activity (pmol/hr/10^5 cells)*	*cAMP content (fmol/10^5 cells)*
Control	13 ± 3	0.5 ± 0.1	65 ± 3
10 μmol/L Forskolin	95 ± 17*	6.9 ± 1.0*	7670 ± 58*
1 μmol/L Methotrexate	30 ± 7	2.5 ± 0.1*	45 ± 2
Analysis of variance	$p < 0.05$	$p < 0.05$	$p < 0.05$

*Values are significantly greater than control by Fisher's multiple comparison method ($p < 0.05$).

drogen precursor to estrogen by a factor of 13.5 (Table II). The combination of forskolin and methotrexate at these doses afforded additive and, in some cases, synergistic effects on aromatase activity, suggesting that the two agents activate different intracellular pathways (data not shown).

Forskolin is a potent activator of adenylyl cyclase.[20] To test whether the effects of this agent on the biochemical cytodifferentiation of BeWo cells was mediated via cAMP, similar experiments were carried out with the use of 1 mmol/L dibutyryl cAMP. After 48 hours, aromatase activity in the presence of dibutyryl cAMP was increased 3.2-fold over control levels, corroborating the results of others.[5] We investigated if the similar phenotype induced by methotrexate might be mediated by an increase in cellular cAMP levels. Using a specific cAMP radioimmunoassay, we were unable to detect an effect of methotrexate on the accumulation of this "second messenger." As expected, forskolin stimulated a large increase (>100-fold) in BeWo cell cAMP content (Table II).

Endocrine gene expression. Consonant with the stimulation of their detectable protein activities, increases in the steady-state levels of the mRNAs encoded by the hCG-β and human aromatase genes were also demonstrated in BeWo cells. By Northern blot analyses,

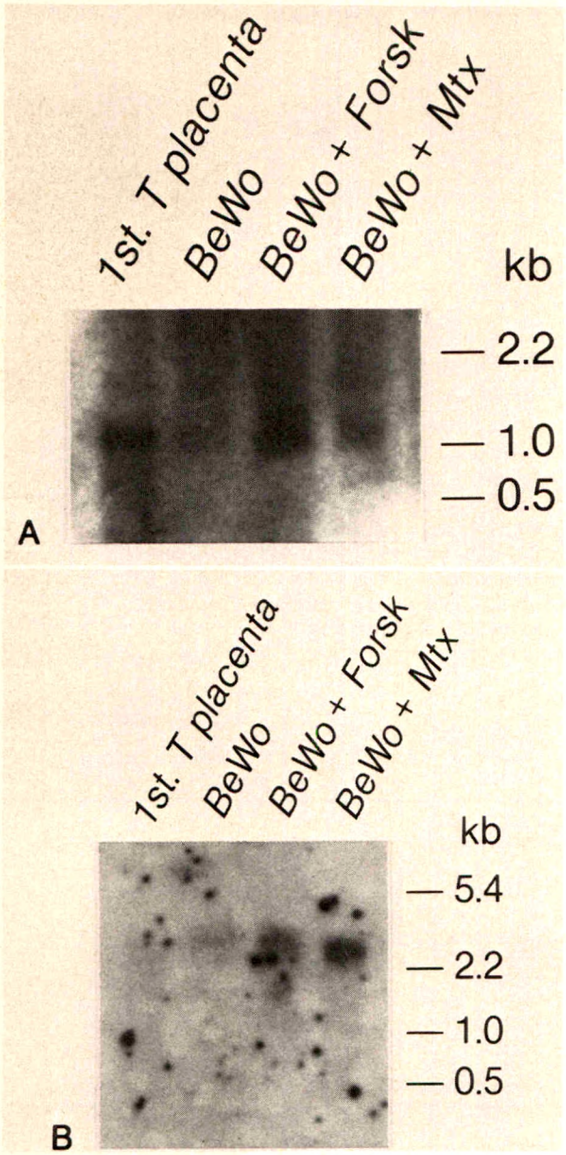

Fig. 3. Northern blot analyses of hCG-β and aromatase mRNA levels in BeWo cell cultures. **A,** Total RNA (10 μg per lane) from control cells *(BeWo)* and cells stimulated with forskolin *(BeWo + Forsk)* or methotrexate *(BeWo + Mtx)* were electrophoresed, blotted, and probed with [^{32}P]cDNA specific for hCG-β. Ten micrograms of normal, first-trimester human placental RNA *(1st. T placenta)* served as a positive control. A representative autoradiogram, revealing the characteristic 1.1 kb transcripts, is shown. **B,** The same Northern blot described in **A** was stripped and hybridized with a [^{32}P]cDNA probe specific for the human aromatase gene. The autoradiogram demonstrated dominant 2.9 kb transcripts. In contrast to the level of expression of hCG (see preceding text), normal, first-trimester placenta did not express significant levels of aromatase mRNA.

a 1.1 kb mRNA species complementary to the hCG-β gene was detected in total BeWo cell RNA. Intact, first-trimester placental tissue, in which high levels of this mRNA are expressed, served as a positive control. Quantification by laser densitometry showed that forskolin increased the concentration of hCG-β mRNA 4-fold, whereas methotrexate stimulated the accumulation of this message by 2.5-fold over basal levels (Fig. 3, *A*). When the Northern blots were probed for human aromatase mRNA expression, a dominant 2.9 kb species was detected. BeWo cells exposed to forskolin and methotrexate expressed this mRNA at concentrations 5- and 7-fold, respectively, over basal levels in unstimulated BeWo cells (Fig. 3, *B*). As expected from the endocrine physiology of the first-trimester placenta, in contrast to its prominent expression of hCG mRNA, levels of aromatase gene expression were barely detectable in this tissue.

Comment

Our findings demonstrate that two chemical agents, very different in structure and known mechanisms, both induce similar changes in the phenotype of cultured human trophoblast cells. BeWo cell stimulation with either forskolin or methotrexate resulted in morphologic and biochemical transformation, which is reminiscent of trophoblast differentiation in vivo. Two observations suggested that these agents operate through independent intracellular pathways. Forskolin is known to activate adenylyl cyclase by binding to the activated complex of its catalytic subunit and the G_s (guanine nucleotide stimulatory) protein.[20] As we have shown, BeWo cells responded to this agent with a dramatic increase in intracellular cAMP levels. Moreover, we and other investigators[5] have documented that cAMP analogs can stimulate estrogen biosynthesis in trophoblast cells, albeit to a lesser extent than forskolin. Activation of cAMP-dependent pathways also increases hCG expression in trophoblast cells.[5-7] Methotrexate, an antimetabolite and inhibitor of reduced folate coenzymes,[21] has complex pharmacologic properties but under the conditions of our studies did not stimulate intracellular cAMP levels. Furthermore, addition experiments using maximally effective doses of forskolin and methotrexate led to additive or synergistic responses in aromatase activity, suggesting that different pathways are involved. Nonetheless, cAMP-independent effects of forskolin, including inhibition of membrane glucose transporters and modulation of voltage-dependent potassium channels, have been documented.[20] Further characterization of these pathways is ongoing to ascertain whether methotrexate and forskolin might share signalling networks in trophoblast cells.

Studies in cultured choriocarcinoma cells have previously documented the effects of cAMP on levels of hCG protein,[5, 6] mRNA,[7, 22, 23] and aromatase activity.[5] In the studies of Lobo et al.,[24] using trophoblast cultures from normal term placenta, dibutyryl cAMP stimulated hCG secretion but not aromatase activity. Ringler et al.[7] also demonstrated subtle differences between the in vitro responses of normal and malignant trophoblast

cells, cautioning that models such as that reported here may not be directly applicable to the process of normal cytotrophoblast differentiation. Nevertheless, the coordinated augmentation of hCG-β and aromatase gene expression in our experiments, as well as its association with cytologic and nuclear differentiation, suggests that the morphologic and biochemical characters of trophoblast may be coupled as described in normal and malignant placental tissue in vivo.[1, 4, 25]

One unexpected observation in these studies was that a single aromatase mRNA transcript of 2.9 kb was detected in the BeWo cells. Previous studies using human term placentas had demonstrated the existence of two aromatase mRNA species (2.5 and 2.9 kb), which are derived from differential processing at alternative polyadenylation sites.[26] Whether the current findings represent preferential expression of the longer transcript in BeWo cells or failure to resolve the two mRNAs is under investigation.

Our experiments demonstrated that forskolin and methotrexate can induce BeWo choriocarcinoma cells in vitro to recapitulate biochemical and morphologic changes consistent with those noted in vivo during normal trophoblast differentiation. These studies extend previous investigations by confirming that two dissimilar xenobiotic agents have similar effects on trophoblast phenotype. That both agents induce a common phenotype supports the hypothesis that intermediate trophoblast represents a discrete step in placental differentiation, which is likely to be modulated in vivo by a variety of differentiation and growth factors. Moreover, our results indicated that the stimulation of hCG-β and aromatase gene expression by these agents was mediated at a pretranslational level. This observation is consistent with the nuclear run-on data of Jameson et al.,[27] which demonstrated that 8-bromo-cAMP enhances the rate of hCG gene transcription in choriocarcinoma cells. The precise mechanisms and pathways activated by forskolin and methotrexate in our BeWo cell model are currently unknown.

Other in vitro models of trophoblast cytodifferentiation[28, 29] suggest that isolated cytotrophoblasts from normal term placenta fuse to generate functional and morphologic syncytia. Recent studies, using isolated normal trophoblasts under serum-free conditions, have documented the development of mature endocrine function in the absence of true syncytium formation.[30] Our model, similar to the latter report, appears to be representative of an intermediate stage of trophoblast cytodifferentiation. In the presence of forskolin or methotrexate, small cytotrophoblast-like BeWo cells enlarged, developed a vacuolated cytoplasm, nuclear swelling, and lobation, and increased prominence of the nucleoli. Within the short time course of our experiments (48 hours), fusion to form true syncytia was not observed. These morphologic findings, as well as the acquisition of mature endocrine functions, are typical of intermediate trophoblast as characterized by Kurman et al.[3] This transitional form of trophoblast cell is believed to be the proximate precursor of the fully functional hormone-producing syncytium. In addition, intermediate trophoblast is thought to play an important role in implantation and the formation of the uteroplacental circulation.[4] We believe that our model system will provide a useful in vitro system to investigate this critical stage of human trophoblast differentiation.

We thank Marion Conn and Cheryl Padula for expert technical assistance, and Drs. Stanley R. Glasser (Baylor College of Medicine), Paul C. Goldsmith (University of California, San Francisco), and Pentti K. Siiteri (University of California, San Francisco) for their helpful suggestions during the course of these experiments.

Factors influencing the initiation of nonshivering thermogenesis

Tania R. Gunn,[a] Karen T. Ball, MSc,[a] Gordon G. Power, MD,[b] and Peter D. Gluckman[a]

Auckland, New Zealand, and Loma Linda, California

The aim of this study was to observe the sequential effects of oxygenation, umbilical cord occlusion, and finally cooling on circulating catecholamines and nonshivering thermogenesis in fetal sheep. We studied five fetal sheep at 132 ± 3 days' gestation. The fetuses were first ventilated with oxygen; Pao_2 levels were maintained above 150 mm Hg, and by 60 minutes there was a significant rise in both plasma glycerol and free fatty acid levels. After umbilical cord occlusion there was a peak in plasma catecholamine and triiodothyronine levels but no significant increase in lipolysis. Cooling, by circulating cold water through a coil around the fetus, induced maximum lipolysis and temperature difference between brown fat and body core, when plasma catecholamine levels were falling. During this study the changes in plasma catecholamine levels did not correlate with the onset of nonshivering thermogenesis. Cutaneous cooling, which causes neurally mediated sympathetic stimulation of brown adipose tissue, is the major signal for the initiation of nonshivering thermogenesis and thus neonatal adaptation. (Am J Obstet Gynecol 1991;164:210-7.)

Key words: Cooling, catecholamines, nonshivering thermogenesis

At birth the fetus is rapidly subjected to cooling, increased oxygenation, and separation from placental blood flow; because these events occur virtually simultaneously, it has not been possible technically to study the effects of the individual factors. In this study we sought to observe separately the effects of oxygenation, β-adrenergic stimulation, occlusion of the umbilical

cord, and cooling of the fetus on the initiation of nonshivering thermogenesis.

Prolonged and intensive cooling of the amniotic fluid and fetal sheep in utero does not stimulate nonshivering thermogenesis,[1] although shivering does occur[2] and fetal plasma catecholamine concentrations rise significantly.[3] Oxygenation of the cooled fetal sheep in utero by ventilation has been shown to stimulate moderate nonshivering thermogenesis, whereas umbilical cord occlusion caused a further rapid increase in fetal plasma glycerol and free fatty acid concentrations.[4]

Significant increases in plasma catecholamine concentrations occur at birth in the human infant and lamb.[5,6] The catecholamine surge induced by umbilical cord cutting has been postulated to be the factor triggering nonshivering thermogenesis at birth.[7] The aim of this study was to evaluate the relative role of a rise in plasma catecholamine levels and of the reflex stimulation of the sympathetic nervous system in the initiation of thermogenesis at birth.

Methods

Surgical procedures. Five Romney ewes carrying lambs from 122 to 140 days' gestational age were operated on while they were under halothane-oxygen general anesthesia. Maternal tarsal arterial and venous catheters and fetal carotid arterial and jugular venous catheters were inserted aseptically. Calibrated thermistors were placed in the maternal vena cava and fetal esophagus to record core body temperature. Another thermistor was placed near a fetal kidney to measure perirenal brown fat temperature. A 5 m coil of plastic tubing was placed around the fetal thorax and neck,[8] and a loop of tape was placed loosely around the umbilical cord. A tracheal cannula (6 mm outer diameter) was inserted and connected to a length of tubing (7 mm inner diameter; dead space 15 ml) for later ventilation of the fetus. The breathing tube, thermistor leads, afferent and efferent arms of the coil, snare, and catheters were exteriorized through an incision in the maternal flank.[4] During the recovery period tracheal fluid was allowed to drain into the amniotic fluid. Experiments were carried out the following day, while the ewes stood in a metabolic cage in the laboratory at 20° C and 50% relative humidity. They were given free access to hay, alfalfa, sheep "nuts," and water throughout the study.

Experimental procedures. Five fetuses were studied. Temperature readings (±0.01° C) were recorded at 1-minute intervals throughout the study, and blood samples were collected at 15-minute intervals. The experiment began with a 30-minute control period. Fluid was then drained from the lungs and the tracheal tube was connected into a closed rebreathing circuit. This circuit consisted of a respiratory pump (Harvard model 607), 1 L spirometer, appropriate one-way valving, and a carbon dioxide absorber.[4] The settings were adjusted periodically to maintain arterial $Paco_2$ in the range 40 to 55 mm Hg and Pao_2 above 100 mm Hg.

After 60 minutes of oxygen ventilation an isoproterenol infusion (0.04 to 0.08 μg/kg/min) was commenced and continued for the next 210 minutes. After 60 minutes of this infusion the snare around the umbilical cord was pulled tight. Ventilation and isoproterenol were continued for a further hour, and then cooling was begun. Passing chilled tap water (8° to 19° C) through the coil at a rate of 180 to 280 ml/min caused the fetal core temperature to fall 2° to 3° C.[8]

To complete the experiment the cooling was stopped, and after 30 minutes of spontaneous rewarming the isoproterenol infusion was discontinued and the thermogenic responses were monitored for a further 30 minutes.

After completion of the study the ewe and fetus were put to death with an overdose of barbiturate. The fetus was weighed to the nearest gram, and the location of the thermistors and occlusion of the umbilical cord were verified. The thermistors were recalibrated to establish that their characteristics had not changed during implantation.

Blood sampling. Fetal carotid arterial blood samples (2.1 ml) were collected anaerobically and promptly analyzed for blood gas and pH values. The plasma was then removed after centrifugation and stored at −20° C for later analysis.

Analytic procedures. pH and Po_2 were measured at 39° C with microelectrodes (Radiometer model BMS-3). Observed values were corrected to the actual body temperature of the fetus at each phase of the experiment.[9] Thyroxine (T_4) and 3,5,3′-triiodothyronine (T_3) were measured by radioimmunoassay. All iodothyronine measurements were made in single assays. The within-assay coefficients of variation were 8.9% for T_4 and 7.7% for T_3. All samples had concentrations appreciably above the limit of sensitivity of the assays. Glycerol was analyzed after enzymatic conversion with glycerokinase according to the method of Pinter et al.[10] Plasma free fatty acids were determined by the colorimetric method of Falholt et al.[11] Palmitic acid was used as a standard, and a sample size of 0.1 ml was used to increase the sensitivity. The within-assay and between-assay coefficients of variation were 2.2% and 4.1% for glycerol and 9.0% and 14.1% for free fatty acids, respectively. Norepinephrine and epinephrine were measured by radioenzymatic assay[12] as described previously.[3] Results are provided as means ± SEM. Statistical comparisons were made after preliminary analysis

Table I. Changes in fetal arterial pH, Pa_{O_2}, and core temperature at intervals during the study: Control, ventilation with oxygen, isoproterenol infusion, umbilical cord occlusion, cooling, rewarming, and discontinuation of isoproterenol

	pH	*P_{O_2} (mm Hg)*	*Temperature (° C)*

Means and SEs for five fetal sheep are given.

of variance between the means at the start of each episode of the study and single experimental values at the end of that episode by use of Student's *t* test.

These procedures were approved by the Animal Ethics Committee of the University of Auckland.

Results

The five fetal sheep were 132 ± 3 days' gestation and weighed 3.2 ± 0.3 kg.

Control period. In the control period the fetal core and brown fat temperatures were in the normal fetal range of 39.74° ± 0.11° C, and they were not significantly different. The fetal core temperature averaged 0.21° C higher than the maternal core temperature. The fetal arterial P_{O_2} was 20.8 ± 1.70 mm Hg and pH was 7.42 ± 0.01 (Table I). Plasma T_3 and T_4 levels, glycerol concentration (57.9 ± 9.0 μmol/L), and free fatty acid levels (37 ± 8 μEq/L) were all in the normal fetal range. Plasma norepinephrine and epinephrine concentrations were 358 ± 124 and 293 ± 136 pg/ml, respectively.

Ventilation with oxygen. Five minutes after the start of ventilation the fetal arterial P_{O_2} rose to 198.2 ± 40.4 mm Hg and was maintained above 150 mm Hg for the next 5 hours. There was no significant change in pH (Table I). There were also no significant changes in fetal or maternal temperatures or in plasma catecholamine or thyroid concentrations. After 60 minutes plasma glycerol levels had risen to 105 ± 2.3 μmol/L ($p < 0.02$) (Fig. 1), and plasma free fatty acids had risen to 97 ± 26 μEq/L ($p < 0.02$).

Isoproterenol infusion. The infusion of the β-adrenergic receptor agonist isoproterenol for 60 minutes did not cause any significant change in fetal temperatures, oxygenation, pH, plasma catecholamine levels or thyroid hormone levels. By 60 minutes plasma glycerol values increased to 183 ± 61 μmol/L ($p < 0.05$) (Fig. 1) and plasma free fatty acids increased to 132 ± 33 μEq/L ($p < 0.04$); significance is after comparison with values after 60 minutes of ventilation.

Umbilical cord occlusion. Snaring of the umbilical cord was followed by a 1.08 ± 1.02° C steady rise in fetal core and brown fat temperature to 40.99° C after 60 minutes. The fetal arterial P_{O_2} was 202 ± 87 mm Hg and pH was 7.15 ± 0.07. There was a significant increase in fetal plasma norepinephrine and epinephrine concentrations to a peak of 2553 ± 937 pg/ml ($p < 0.05$) (Fig. 2, *A*) and 2409 ± 990 pg/ml ($p < 0.05$), respectively, after 60 minutes of cord occlusion (Fig. 2, *B*). The plasma T_3 concentrations rose to 1.14 ± 0.31 nmol/L ($p < 0.01$) whereas the plasma T_4 levels were unchanged (Fig. 3). The plasma glycerol concentration was 286 ± 81 μmol/L, and the free fatty acid level was 194 ± 35 μEq/L (not significant compared with the previous period).

Cold exposure. Fetal core temperature fell 3.53° ± 0.56° C after 60 minutes of cooling while brown fat temperature fell 2.54° ± 0.56° C during this period. The fetal brown fat minus core temperature difference had increased to 0.99° ± 0.35° C ($p < 0.01$), indicating vigorous nonshivering thermogenesis (Fig. 1). The fetal arterial P_{O_2} was 151.7 ± 30.6 mm Hg, and there was an increasing acidosis (pH 7.08 ± 0.04) after 60 minutes of cooling. The plasma norepinephrine and epinephrine concentrations fell during cold exposure ($p < 0.05$) (Fig. 2), whereas there was no change in thyroid hormone levels (Fig. 3) during this period. After 60 minutes of cooling the plasma glycerol levels had risen a further twofold to a peak of 551 ± 190 μmol/L ($p < 0.05$) (Fig. 1) and the free fatty acid concentrations to 313 ± 79 μEq/L ($p < 0.04$).

Warming and discontinuation of isoproterenol. The fetal core and brown fat temperatures returned to control values during this period. The arterial P_{O_2} was 270 ± 13 mm Hg and pH was 7.40 ± 0.03 at the end of the study. The plasma glycerol concentrations fell to 181 ± 72 μmol/L ($p < 0.02$) and free fatty acid levels fell to 87 ± 38 μEq/L ($p < 0.03$) whereas the fetal brown fat minus core temperature decreased rapidly ($p < 0.01$) (Fig. 1). Only the plasma T_3 levels remained

elevated (Fig. 3). Catecholamine levels remained at basal values.

Comment

Effective thermogenesis is essential for successful neonatal adaption to extrauterine life. In the preterm sheep in utero we have studied the effects of sequentially ventilating the fetal lungs with oxygen, infusing a β-adrenergic agonist, occluding the umbilical cord, and finally cooling the fetus. The order in which these events are applied to the fetus is important. In our previous studies we introduced the stimuli in a different order, commencing with cooling, followed by oxygenation and finally umbilical cord snare.[4, 13] No effect of cooling alone on lipolysis could be demonstrated. We found a modest increase in plasma free fatty acid and glycerol levels after oxygenation and a marked increase in these levels after umbilical cord snare. There was a lack of a thermogenic response to cooling alone, although fetal plasma catecholamine concentrations and blood flow to the fetal brown fat increased significantly.[3, 14]

In this study in which the sequence of events was altered, ventilation with oxygen in the absence of cooling caused a small but significant increase in plasma glycerol and free fatty acid concentrations, and infusion of the β-adrenergic receptor agonist isoproterenol caused a further modest rise. The lack of an α_1-adrenergic action by isoproterenol may explain this modest response of plasma glycerol and free fatty acids as there appears to be a synergistic interaction between β-adrenergic and α-adrenergic receptor stimulation during thermogenesis.[15, 16] Alternatively, those agonists circulating in the blood may be appreciably less effective than those released from nerve endings in brown adipose tissue.

Umbilical cord occlusion was followed by only a small further rise in plasma glycerol and free fatty acid levels despite a very marked surge in circulating levels of norepinephrine and epinephrine, both of which are mixed β- and α-adrenergic agonists.[17] Recently attention has focused on circulating catecholamines as the dominant signal for the onset of lipolysis at birth. Padbury et al.[7, 18] demonstrated in acutely exteriorized fetal sheep that circulating plasma catecholamine levels rose substantially after umbilical cord cutting, in association with a rise in plasma free fatty acid levels. A greater sympathoadrenal response was found in preterm sheep than in term sheep, with a delayed but exaggerated elevation of both plasma norepinephrine and epinephrine levels but blunted free fatty acid responses.[17] In our study of preterm fetal sheep in utero, where the various events of parturition can be independently evaluated, the timing and levels of peak norepinephrine plasma concentrations after umbilical cord occlusion

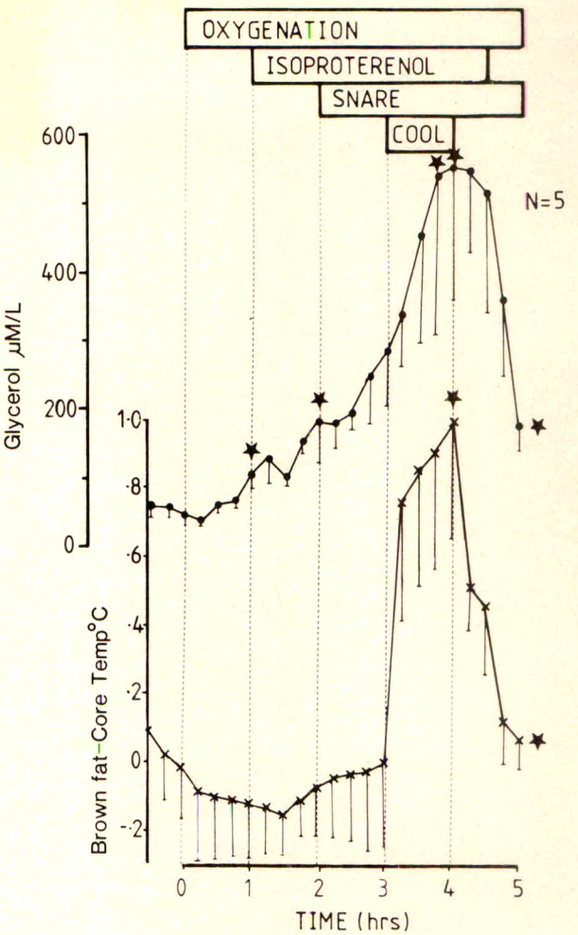

Fig. 1. Time course and responses of plasma glycerol concentrations and fetal brown fat minus core temperature is shown after ventilation with oxygen, infusion of isoproterenol, occlusion of the umbilical cord, cooling, and then rewarming. Means and SEs for five fetal sheep are given. *Star*, $p < 0.05$.

were similar to those found by Padbury et al.[18] after umbilical cord cutting whereas the peak plasma epinephrine concentration was lower and earlier. However, the values achieved were in excess of those suggested to be sufficient to initiate physiologic responses.[19] This study therefore strongly suggests that changes in circulating catecholamine levels are not causal in the initiation of nonshivering thermogenesis because the surge in plasma catecholamines did not correlate with changes in indices of thermogenesis and points to other factors as major determinants of nonshivering thermogenesis at birth.

Cooling after cord snare rapidly induced marked lipolysis with a noticeable increase in the fetal brown fat minus core temperature differential. This occurred while catecholamines were decreasing, whereas earlier in the experiment, when catecholamines peaked, thermogenesis was not maximal. The most likely explana-

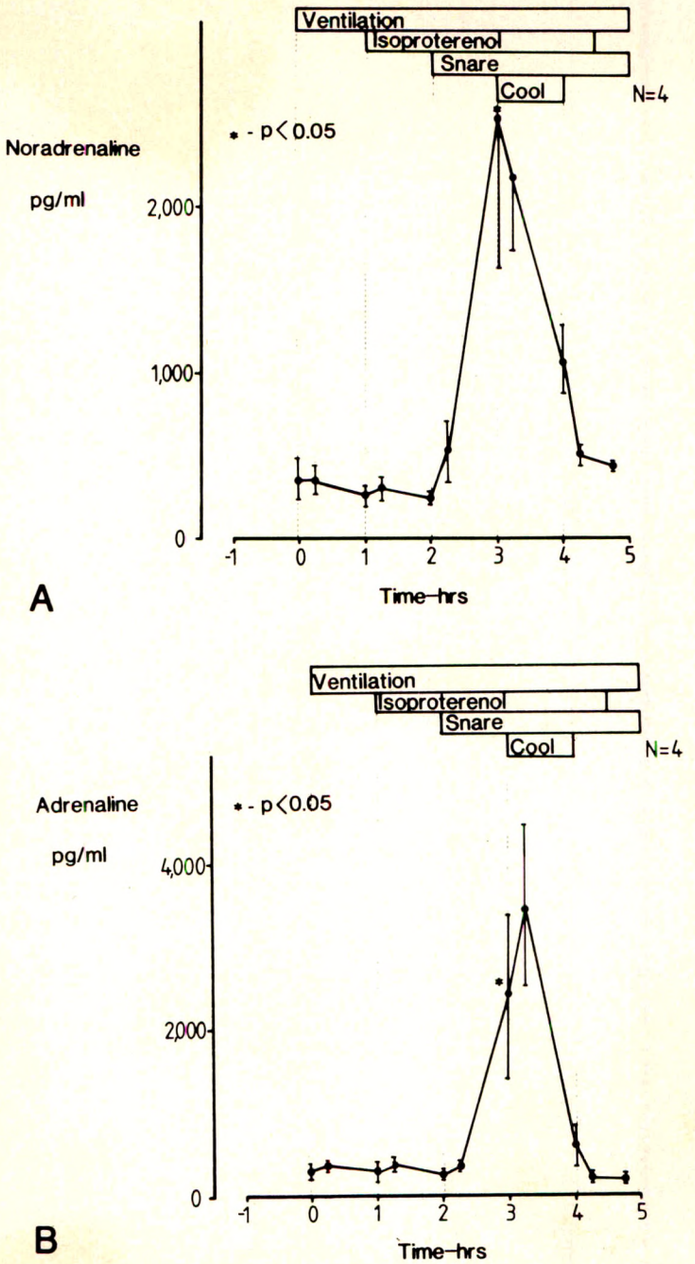

Fig. 2. A, Time course and responses of plasma norepinephrine concentrations are shown after ventilation, isoproterenol infusion, umbilical cord occlusion, cooling, and rewarming. tion for this is that cooling induced an increased drive via the sympathetic nervous system leading to noradrenergic stimulation of lipolysis via direct innervation of brown fat. Stimulation of the sympathetic nervous system by cold exposure markedly increases norepinephrine turnover in brown adipose tissues,[20, 21] which may not be reflected by a rise in circulating catecholamine levels. Indeed the role of nervous rather than endocrine regulation of brown fat is supported by studies in the newborn lamb. Agata et al.[22] demonstrated that the majority of circulating norepinephrine in the lamb at birth arises from postganglionic sympathetic neurons. In a previous study we found that changes in plasma catecholamine levels did not parallel changes in

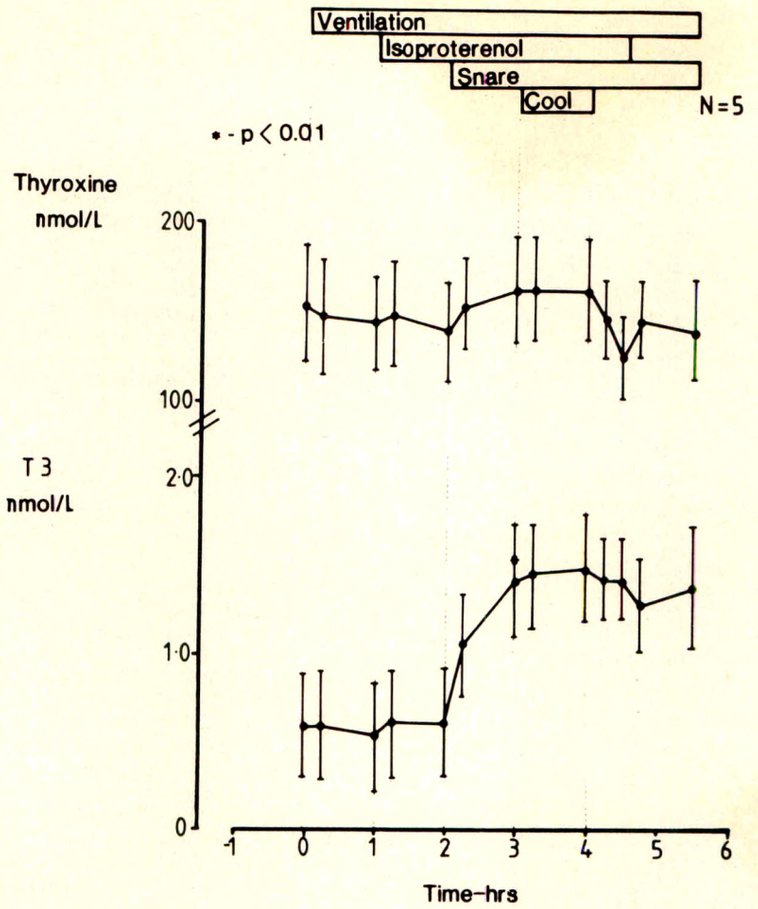

Fig. 3. Responses of plasma thyroxine and T_3 are shown after ventilation, isoproterenol infusion, umbilical cord occlusion, cooling, and rewarming. Means and SEs for five preterm fetal sheep are given.

thermogenic indices.[13] Further adrenalectomy in infant lambs reduced summit metabolism after cold exposure; this was restored by cortisol to 85% of the response in intact animals, and the influence of circulating catecholamines appeared to be small.[23] Such neurally mediated, local control of brown fat agrees with observations that β-adrenergic and ganglionic blockade inhibits ≥80% of nonshivering thermogenic responses in the fetal sheep.[24] Thus it seems clear that sympathetic nerve activity is both necessary and able to explain the onset and control of nonshivering thermogenesis in the fetal sheep.

Removal of the placental circulation by cord occlusion appears to act passively and allows cooling-induced sympathetic activity in brown fat to initiate heat production. Recent evidence suggests that the passive effect of placental separation is due to removal of placental factors that enter the fetal circulation and inhibit nonshivering thermogenesis.[4] The presence of such inhibitors seems to be of benefit to successful neonatal adaptation. If the marked increases in fetal circulating catecholamine levels that have been shown to follow hypoxia[25] and labor[26] induced nonshivering thermogenesis in utero, the increased oxygen demand and heat production would seriously compromise the metabolic state of the fetus. The concentrations of these inhibitory factors fall after cord occlusion, thereby permitting thermogenesis to begin when cooling stimulates sympathetic nerve activity. This study indicates that such an inhibitor might act by blocking sympathetic stimulation of brown fat but it does not identify the site of action.

The euthyroid state in late gestation is necessary for effective thermogenesis. Lambs that underwent thyroidectomy in midgestation become profoundly hypothermic and die after delivery[27]; the serum free fatty acid levels are reduced despite elevated plasma epinephrine concentrations.[28] However, thyroidectomy performed during delivery but before the umbilical cord is severed does not impair the increase in oxygen consumption although the postnatal surge in plasma T_3 is arrested.[29] A thyrotropin surge occurs soon after

birth in human infants,[30] and this also occurs rapidly after the fetal sheep is cooled in utero.[31] The only intervention that caused a significant rise in plasma T_3 concentrations in our study was umbilical cord snare; cooling caused no further increase. A rise in plasma T_3 after cord cutting or snare has been reported.[4, 32] This rise in plasma T_3 may be due to removal of placental inner ring monodeiodinase activity,[33] with an increase in T_4 to T_3 conversion in brown adipose tissue.[34] In our study the failure of circulating T_3 to rise further after cooling was begun and nonshivering thermogenesis was activated speaks against brown fat as a major site of origin of circulating T_3 in the lamb. In brown adipose tissue type II 5′-deiodinase activation is induced by cold exposure,[34, 35] and this enzyme increases intracellular conversion of T_4 to T_3. In rats this local production of T_3 defines the rate of synthesis of uncoupling protein (thermogenin) in brown adipocytes and thus promotes nonshivering thermogenesis.[34] Full expression of the uncoupling protein gene in the brown adipocytes of the rat, in which nonshivering thermogenesis is induced over some days after birth, requires both norepinephrine and T_3. However, in both sheep and man, where nonshivering thermogenesis is initiated immediately at birth, brown fat may be recruited before parturition. This may be induced in part by the gradual rise of T_3 in fetal lambs in late gestation.[36] This would explain the effect of fetal, but not neonatal, thyroidectomy on the initiation of nonshivering thermogenesis. Further, thermogenin messenger ribonucleic acid can be demonstrated in brown fat in late gestation in the bovine and other species with immediate onset of nonshivering thermogenesis.[37]

In conclusion, in the present study plasma free fatty acid and glycerol levels rose to values 10 times greater than control concentrations and to about 80% of the levels achieved in cold stressed newborn lambs.[38] These were comparable to those in prematurely delivered lambs, which have lower rates of nonshivering thermogenesis than term lambs.[39]

Many factors are important for the initiation of effective nonshivering thermogenesis at birth; these include cutaneous cooling, oxygenation, separation from the placenta, and the euthyroid state. The surge of circulating catecholamines after umbilical cord occlusion is not the major signal. Stimulation of the sympathetic nervous system plays a dominant role in the initiation of thermogenesis in response to cold cutaneous receptor stimulation.

We thank Dr. M. G. Nicholls, Princess Margaret Hospital, Christchurch, New Zealand, for the catecholamine assays.

Transplantation of fetal cells

Timothy M. Crombleholme, MD, Jacob C. Langer, MD, Michael R. Harrison, MD, and Esmail D. Zanjani, PhD

San Francisco, California, and Reno, Nevada

Cellular transplantation is an attractive alternative to whole-organ transplantation when only a discrete function of the organ is deficient. Early fetal donor cells have an advantage because they engraft readily and do not cause graft-versus-host disease. Similarly, the fetus is an ideal recipient of allogeneic fetal cells as it is incapable of rejecting them early in gestation. This review presents the theoretical rationale, recent research advances, and clinical implications for adults with diabetes mellitus and Parkinson's disease; we also describe in utero transplantation of fetal hematopoietic stem cells and hepatocytes for the treatment of inherited hemotologic and hepatic deficiencies, as well as the use of fetal islet cells and dopamine-producing cells to treat postnatal conditions. (Am J Obstet Gynecol 1991;164:218-30.)

Key words: Cellular transplantation, graft-versus-host disease, hematopoietic stem cells

Cellular transplantation has long been considered as a possible alternative to whole-organ transplantation for a variety of tissues. Cellular transplantation has the potential advantages of technical ease, placement of cells into an immunologically or physiologically advantageous location, ability to manipulate the cells in culture before transplantation, and convenience of long-term cryopreservation of viable cells. In experimental systems encouraging results have been seen with transplantation of hematopoietic stem cells, pancreatic islet cells, and hepatocytes. However, except for the relatively recent advances in bone marrow transplantation, cellular transplantation has not been widely used clinically.

The use of fetal tissue for transplantation has a number of theoretical advantages. The most important is the potential immunologic "immaturity" of fetal tissue, a concept that arises from the presumption that the recognition of "self" occurs during an early stage of fetal life and that tissue used before that stage would be immunologically privileged. Work in the mouse model has shown that H-2 antigens are expressed at 11 days' gestation, implying that fetal tissue used before that time would not be rejected.[1] Further evidence to support this contention was reported by Foglia et al.,[2] who found in a rat model that transplants of fetal renal tissue were more readily accepted earlier in gestation than later. In addition, they found in their model that graft survival was worse with hepatic tissue than with gonadal and renal tissue, leading them to the conclusion that rejection of fetal grafts is also organ specific.

There are currently several types of fetal cellular transplantation being investigated experimentally: hematopoietic stem cells, pancreatic islet cells, dopamine-containing neuronal cells, and hepatocytes. Although the functional and immunologic advantages of fetal cells have been useful experimentally and clinically in the treatment of adult patients with hematologic, endocrine, metabolic, and neurologic disorders, fetal cellular transplantation also has been used recently in the treatment of these deficiencies in utero.

Fetal hematopoietic stem cell transplantation

Postnatal allogeneic bone marrow hematopoietic stem cell transplantation has been used to successfully treat a broad spectrum of congenital hematologic diseases (Table I). In most cases, however, donors with identical human leukocyte antigen are not available, precluding transplantation. In addition, by the time most of these children are considered for transplantation, they have already been compromised by disease. Recurrent infections, growth retardation, and sensitization by multiple blood transfusions can reduce the likelihood of a successful outcome. Finally, such allogeneic transplants require recipient bone marrow–conditioning regimens that include radiation or chemotherapy with the attendant risks of infection and

6/1/19059

failure of engraftment. Graft rejection and graft-versus-host disease are constant threats that require long-term immunosuppression. The combination of the disease and its treatment result in high morbidity and mortality for the pediatric recipient.[3-5]

The transplantation of preimmune fetal hematopoietic stem cells into a preimmunocompetent fetal recipient may allow the creation of a permanent hematochimera without the risks of marrow ablation, rejection, and graft-versus-host disease seen in postnatal bone marrow transplantation. Even partial expression of normal hematopoietic stem cells may be enough to ameliorate or eliminate the clinical manifestations of defective cells.[6] For individuals with inherited defects in bone marrow–produced cell lines that can be diagnosed by chorionic villus sampling (e.g., hemoglobinopathies, immunodeficiencies),[7] reconstitution with a normal cell line early in gestation has many theoretical advantages and considerable clinical appeal.[8]

Experimental work

Some animal research has been done, but many questions remain. The work of Seller and Polani[9] demonstrating experimental chimerism in the mouse has been criticized by others[10] because the histocompatibility differences between the donor and recipient were not clearly established. The work of Fleishman and Mintz[11] is provocative, but others have had difficulty reproducing these results, primarily because of problems with injecting a cell preparation into the placenta of a fetal mouse. The investigation of methods to minimize graft-versus-host disease (by depleting donor material of immunocompetent lymphocytes by density gradient perfusion,[12] agglutination on columns,[13, 14] or treatment with monoclonal antibodies[4, 15]) has been hampered because graft-versus-host disease in the mouse model is not as severe and it is not the same disease as in the human; neither Seller and Polani[9] nor Fleishman and Mintz[11] reported graft-versus-host as a complication from allogeneic fetal hematopoietic stem cell transplants in their studies of mice.

In utero hematopoietic stem cell transplantation in sheep

Our goal in this study was to produce an animal model of hematopoietic chimerism by the in utero transplantation of fetal hematopoietic stem cells. We chose the sheep for the following reasons: (1) The sheep has two naturally occurring alleles at the β-hemoglobin locus (A and B) that can be used as definitive markers of successful engraftment and chimerism; (2) gestation in the pregnant ewe is sufficiently long (term = 145 days) to allow experimental manipulation in the first trimester; (3) the immune status of the fetal lamb is relatively well documented, permitting accurate selection of preimmune donors and recipients. We transplanted hematopoietic stem cells obtained from the combined livers of 35- to 50-day-old fetal AA sheep and 45- to 65-day-old homozygous BB fetuses via the intraperitoneal route (Fig. 1). Fetal liver hematopoietic cell suspensions were prepared and injected (2 to 5 × 10^8 cells per kilogram estimated fetal weight) into the peritoneal cavity of fetuses exposed by the amniotic bubble technique (Fig. 2).

Table I. Congenital hematologic diseases successfully treated by postnatal bone marrow transplantation and potentially amenable to in utero hematopoietic stem cell transplantation

β-Thalassemia[3]
Sickle cell anemia[4]
Wiskott-Aldrich syndrome[5]
Chronic granulomatous disease[7, 8]
Kostman's syndrome[10]
Infantile malignant osteopetrosis[11]
Chediak-Higashi syndrome[12]
Maroteaux-Lamy syndrome[13]
Severe combined immunodeficiency syndrome[14]

As with all surgical procedures on the fetus early in gestation, there was a high perioperative mortality. Four fetuses survived the procedure. Of these, three were born with clear evidence of donor cell engraftment as determined by both hemoglobin (Table II) and chromosome (Table III) analysis. This study represented the first successful creation of experimental chimerism in a large animal model, without the use of immunosuppression and without the development of graft-versus-host disease.

We then documented that the donor stem cells primarily engraft in the host marrow and undergo proliferation without significant differentiation until the time during ontogeny when marrow assumes an important role in hematopoiesis.[16] Donor cells obtained from livers of twin 120-day-old fetal sheep homozygous for type A hemoglobin were injected into preimmune (55 to 62 days old) type B fetuses intraperitoneally (6×10^6 nucleated cells per kilogram), and bone marrow, liver, and peripheral blood cells of hosts were analyzed for presence of donor hemoglobin and hematopoietic progenitors at intervals after transplant. Nine of 14 surviving fetuses-lambs exhibited significant donor cell engraftment. About 91% of all donor stem cells detectable by in vitro clonal assays were present in host marrow. At 15 days after transplant, donor erythroid progenitors constituted about 12% of all host marrow colony-forming units, erythrocyte–burst-forming units, erythroid. Although relative percentage of donor colony-forming units, erythrocyte–burst-forming units, erythroid remained unchanged at days

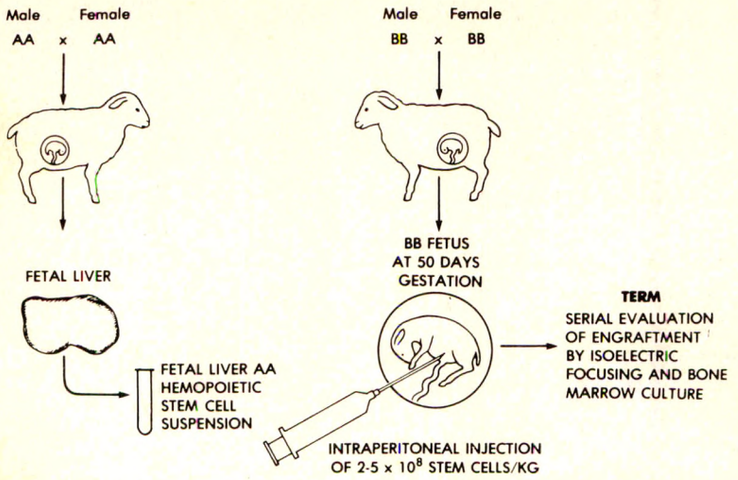

Fig. 1. The sheep model for in utero hematopoietic stem cell transplantation used a naturally occurring polymorphism at the β-hemoglobin locus. Fetal livers were harvested as a source of hematopoietic stem cells from sheep with pure type AA β-hemoglobin. These type AA hematopoietic stem cells were then injected intraperitoneally into a recipient fetus of β-hemoglobin phenotype BB. This polymorphism allowed identification of donor hemoglobin in the postnatal recipients by hemoglobin electrophoresis.

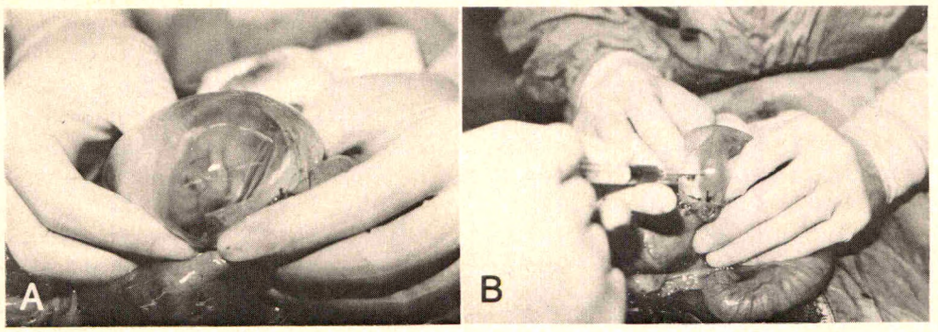

Fig. 2. A, The microbubble technique was used to perform hematopoietic stem cell transplants. The myometrial layers are divided with electrocautery and care is taken to preserve the amnion intact. The fetus can then be manipulated under direct vision. **B,** Injection of hematopoietic stem cells into peritoneal cavity of fetal sheep recipient is easily accomplished.

40 and 70 after transplantation and at 1 month after birth, their absolute numbers in marrow (calculated per femur) increased by 30%, 85%, and 420%, respectively. No donor hemoglobin was detected in host blood on days 15 and 40 after transplantation. Donor hemoglobin in host blood was first detected at day 70 after transplant, close to the time when marrow becomes a major blood cell–producing tissue in sheep. Both at birth and at 1 month after birth, donor hemoglobin constituted about 11% of total blood hemoglobin (Fig. 3).

Our results in the allogeneic hematopoietic stem cell transplant experiments demonstrate that a significant portion of the recipient fetuses exhibited sustained engraftment of allogeneic donor cells, providing support for the concept that the fetus is an ideal recipient for hematopoietic stem cell transplantation. The absence of graft-versus-host disease in long-term chimeric lambs suggests that the preimmune animal is also the ideal stem cell donor.

Fetal hematopoietic stem cells as a vehicle for gene transfer

W. French Anderson and collaborators at the National Institutes of Health have been developing gene therapy as another potential mode of treatment for genetic disease.[17] They have shown that retroviral vectors designed to carry heterologous genes are effective in delivering functional genes into many cell types in vitro[18, 19] and into mouse hematopoietic cells in vitro.[20, 21] We are participating in a study on gene transfer in the lamb that further illustrates that the fe-

tus may be an ideal donor-recipient of hematopoietic stem cell transplants.[22]

To test the feasibility of fetal hematopoietic stem cell–gene transfer, an in utero sheep gene transfer protocol was established. Circulating hematopoietic cells from a 100-day-old fetal lamb were removed by exchange transfusion, injected with N2 vector by the supernatant infection protocol, and reinfused back into the lamb. The fetal lamb was allowed to grow in utero and was born normally at term (145 days' gestation). One week after birth, bone marrow cells from the lamb were evaluated in colony assays in the presence or absence of G418. However, G418 colonies were obtained in the infected animal (colony-forming units, culture = 22%; colony-forming units, mixed = 39%; burst-forming units, erythroid = 35%; colony-forming units, erythrocyte = 22%), representing successful expression of G418 resistance 62 days after transplantation. Whether this represents true expression of the Neo gene awaits further studies.

These preliminary experiments demonstrated that fetal sheep stem cells can be infected efficaciously. It was not clear whether this high level is due to species differences or to an inherent quality of fetal cells or to both. To assay whether the high degree of gene transfer in this model was caused by a greater efficiency of Neo transfer into fetal than adult progenitors, we compared the relative rate of Neo into fetal and adult hematopoietic cells of sheep and the human.[23] Equivalent numbers of adult or fetal cells were incubated with N2-containing supernatant overnight, washed, and cultured in clonogenic assay with and without G418 (2 mg/ml). The infected control cells failed to produce hematopoietic colonies in the presence of G418. In contrast, Neo-infected sheep and human cells produced G418-resistant colonies (Table IV). Overall, fetal cells exhibited a significantly higher degree of Neo transfer than adult hematopoietic cells. There also appeared to be species differences as the effciency of gene transfer was higher in the sheep than the human cells. The gene transfer of Neo into human cells could be dramatically augmented, however, by incubation with a mixture of recombinant human interleukin IL-3 and granulocyte-macrophage colony-stimulating factor in addition to the retroviral vector. The number of adult and fetal resistant colonies (except colony-forming units, erythroid) increased by 300% and 184%, respectively. The greater efficiency of exogenous gene transfer into hematopoietic progenitors further supports the fetus as an ideal donor, in this case for in utero gene therapy.

These findings suggest that in utero transplantation–gene transfer may provide a viable adjunct to postnatal gene transfer or even an alternative when diagnosis is

made in utero. However, the sheep model may not be applicable to the human, so these findings, although encouraging, must be reproduced in a nonhuman primate model.

In utero hematopoietic stem cell transplantation in primates

Although the sheep model has provided many insights into fetal hematopoietic stem cell transplantation, application of these findings in humans is severely limited because sheep gestational physiology and immunology are so dissimilar from those of humans. Before this promising technique could be applied clinically, we felt that feasibility, safety, and efficacy would have to be demonstrated in the nonhuman primate, whose developmental biology and immunologic development are most similar to the human. We have subsequently established the feasibility of an in utero hematopoietic stem cell transplantation in fetal rhesus monkeys at 60 days of gestation.[24, 25]

The research plan is outlined in Fig. 4. Time-dated, pregnant rhesus monkeys *(Macaca mulatta)* were obtained from the California Primate Research Center at the University of California, Davis. Fetectomy was performed at 59 to 68 days of gestation and the liver was harvested as a source of hematopoietic stem cells. Donor cells were prepared by the same technique used in sheep hematopoietic stem cell transplant recipients. Aliquots at a final concentration of 1×10^7 nucleated cells were separated and frozen in 10% dimethyl sulfoxide and fetal calf serum until used. Each recipient fetus received 10^8 to 10^9 cells per kilogram of estimated fetal body weight. The sex of donor fetuses was determined by anatomic dissection at the time of liver harvest. The sex of all but three of the recipient fetuses was determined before transplantation by chorionic villus sampling and direct-preparation karyotype analysis (Fig. 5) or by ultrasonography (Fig. 6), and these received cells from donors of the opposite sex. The sex of three other recipient fetuses was not known at the time of donor cell infusion; these fetuses received an equal mixture of cells from male and female donors. Transplantation of donor cells (10^8 to 10^9 cells per kilogram of fetal weight in 1 ml volume) was performed by injection into the recipient fetus through a 25-gauge spinal needle placed into the fetal peritoneal cavity under ultrasonographic guidance (Figs. 7 and 8).

In utero hematopoietic stem cell transplantation was performed in five fetal rhesus monkeys at 60 days' gestation. Five of the six monkeys with transplants survived to term. The first transplant attempted at the 60 days' gestation time point (No. 17908) was observed to have abruptio placentae during the injection and spontaneously aborted. Three of the five hematopoietic stem cell transplant recipients surviving to term are alive and well 3 to 20 months of age without evidence of graft-versus-host disease by physical examination, liver function tests, and lip biopsy. One rhesus monkey died

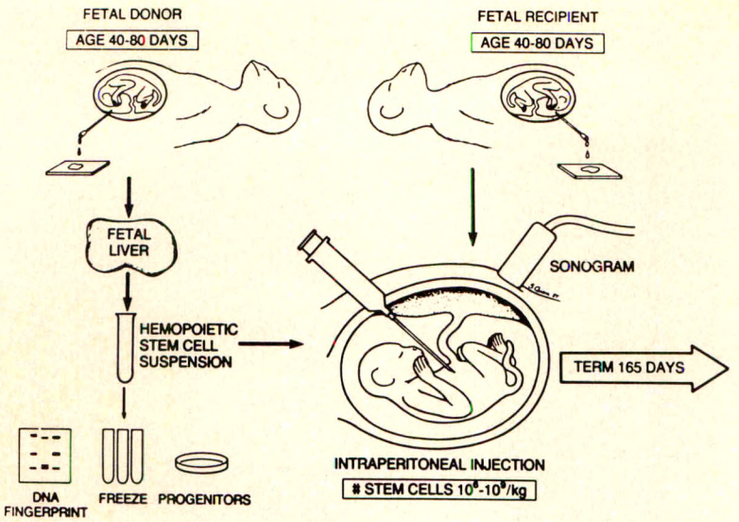

Fig. 4. In rhesus monkey model for in utero hematopoietic stem cell transplantation, there was no naturally occurring polymorphism to allow postnatal identification of donor cells. For that reason only cross-sex transplants were performed, that is, male donor in female recipient and vice versa. Sex of fetal donor was determined by anatomic dissection at the time of fetectomy. Sex of recipient fetus was determined by ultrasonography (if later than 70 days' gestation) or direct-preparation karyotype analysis of a chorionic villus (if earlier than 70 days' gestation). Fetal hematopoietic stem cells were cryopreserved until transplantation was performed by intraperitoneal injection under ultrasonographic guidance.

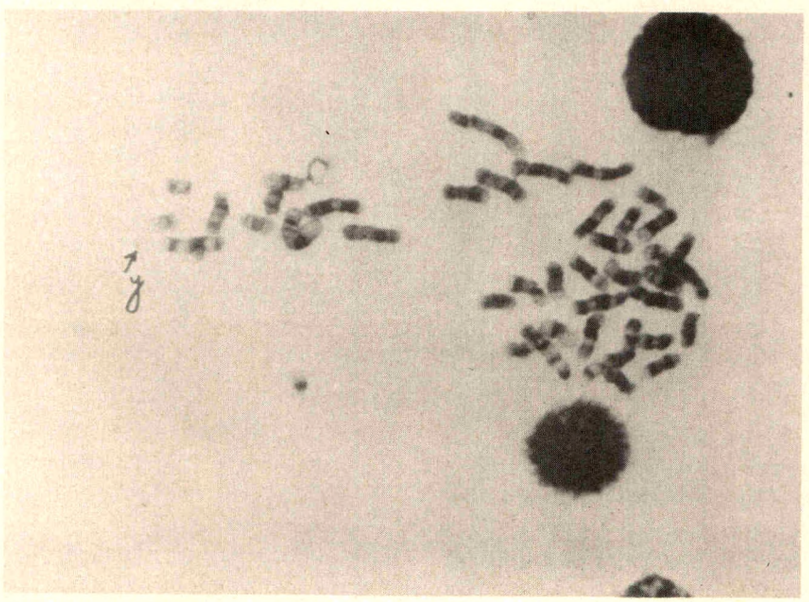

Fig. 5. Karyotype analysis of chorionic villi prenatally, and peripheral blood leukocytes and bone marrow cells allowed the identification of donor cells of opposite sex to the recipient.

shortly after birth of sepsis from chorioamnionitis despite emergency cesarean section. A second rhesus monkey died at 2 weeks of age of severe enteritis, which is endemic in the primate colony.

Hematopoietic stem cell transplants were successful as evidenced by significant levels of donor hematopoietic cell lines detected in recipients.

The pluripotential nature of the fetal hematopoietic stem cell is demonstrated by hematopoietic chimerism found in lymphoid, erythroid, and myeloid cell lines.

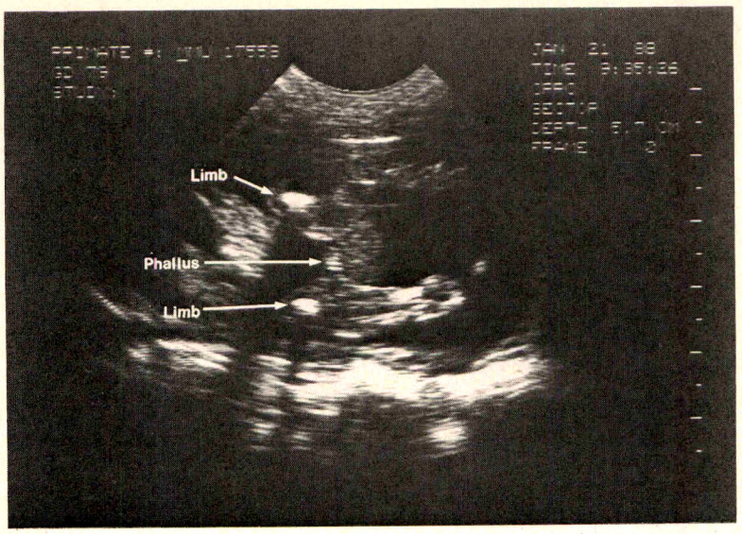

Fig. 6. Ultrasonographic image of fetus with visible phallus confirming male sex.

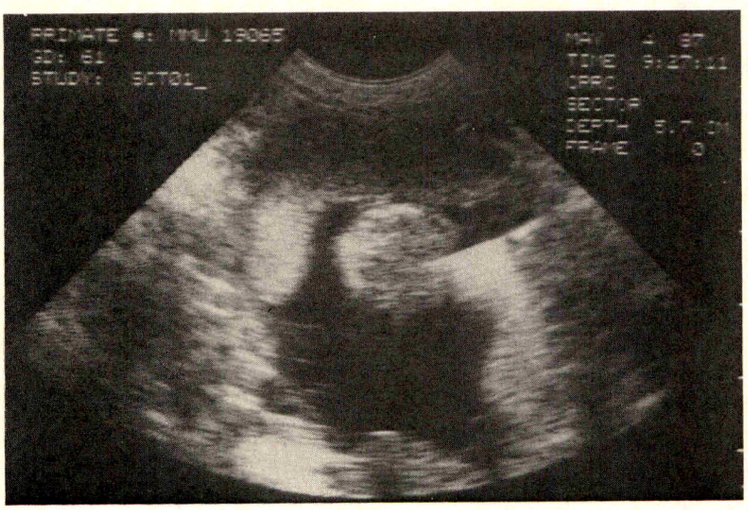

Fig. 7. Ultrasonographic image of hematopoietic stem cell transplantation demonstrating placental disk superiorly and the fetal abdomen in cross section with needle entering peritoneal cavity from right.

In all cases the presence of donor hematopoietic progenitors in the recipient bone marrow was accompanied by the presence of donor cells in the recipients' peripheral blood (Table V), suggesting functional expression of the engrafted donor stem cells. The engraftment in these hematopoietic chimeras has been stable for long periods of time without loss of progenitors from bone marrow or functional expression in peripheral blood (Fig. 9).

Surveillance tests for clinical and subclinical graft-versus-host disease including liver function tests and lip biopsies have been normal. There appears to be complete tolerance of the host by the graft and vice versa. Extensive postmortem histologic examination of the recipients that died in the newborn period (Nos. 19451 and 23857) revealed no evidence of graft-versus-host disease.

The ability of a preimmune fetal recipient to maintain sustained engraftment and expression of donor hematopoietic stem cells throughout gestation and after birth is dependent on its becoming immunologically tolerant of the allogeneic hematopoietic stem cells.[26, 27] Fetal tolerance resulting in permanent chimerism has been shown to occur in nature in twins with shared placental circulation[26, 27] and has been experimentally induced in animal models.[28, 29] Little is known about when in gestation and by what mechanism tolerance is lost. Our results in rhesus monkeys suggest that tolerance

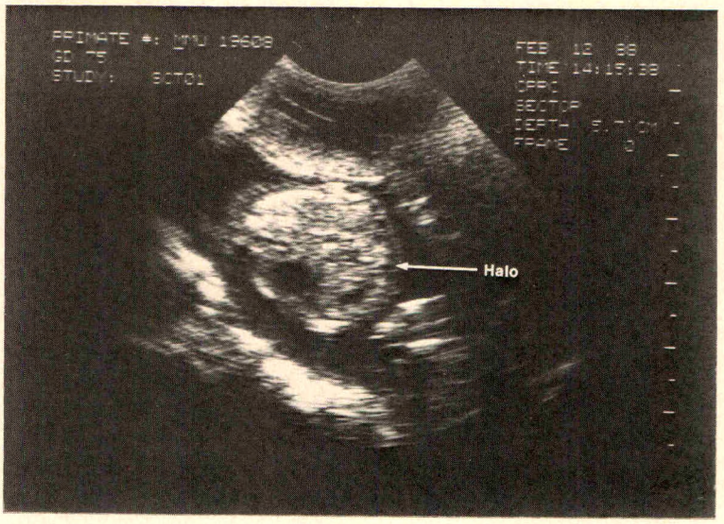

Fig. 8. Postinjection ultrasonographic image demonstrating peritoneal "halo" effect confirming intraperitoneal location of hematopoietic stem cell suspension.

persists until at least 68 days' gestation (~16½ weeks in human gestation). The most important advantage of using fetal hematopoietic stem cells as donor material is that graft-versus-host disease may be ameliorated or eliminated. None of our chimeric sheep[30] or our chimeric monkeys have evidence of graft-versus-host disease. If the preimmune fetal recipient is tolerant of a graft, it follows that donor preimmune hematopoietic stem cells from fetuses of the same gestational age or younger should be tolerant of the recipient. The use of preimmune fetal hematopoietic stem cells for in utero transplantation may obviate three of the most serious problems with postnatal bone marrow transplantation: the need for ablation of the native bone marrow, the possibility of graft rejection, and the threat of graft-versus-host disease.

In utero transplantation of fetal hematopoietic stem cells in rhesus monkeys has proved technically feasible without need for ablation of native marrow or for long-term immunosuppression. Engraftment without rejection or graft-versus-host disease suggests that tolerance to foreign antigen can be induced by at least 68 days' gestation in the rhesus monkey (approximately 16½ weeks in human gestation). The techniques used for in utero hematopoietic stem cell transplantation in rhesus monkeys can be readily applied in humans and may offer the first effective therapy of genetic disorders in utero.

Transplantation of fetal islet cells

Diabetes mellitus is a common disease that is a major source of morbidity and early death. Long-term management with insulin is possible, but perfect control of blood glucose (which appears to be necessary for the prevention of angiopathy) can be provided only by functioning pancreatic islet cells. For this reason there have been many attempts over the past 25 years to develop islet cell transplantation as a therapeutic modality.

Pancreatic islet cells have been used both as whole-organ and as cellular transplants, and both postnatal and fetal donor tissue has been used. Fetal tissue was initially thought to have several advantages: It was thought to be less immunogenic; the fetal pancreas has a higher proportion of islet cells to exocrine cells, and

*Karyotype analyses performed at 1 month of age. Chromosomal analysis of lymphoid cells was performed on peripheral blood cells. Bone marrow cells cultured in the presence of erythropoietin represented the erythroid cell line. Percentage of donor myeloid cells was determined in cultures of bone marrow cells with monkey phytohemagglutinin-leukocyte–conditioned media.

†These rhesus monkeys received an equal mixture of male and female donor cells. The percentage of donor cells given was derived on the basis of the assumption that donor cells of both sexes engrafted similarly; the actual observed amount is 50% of the indicated value.

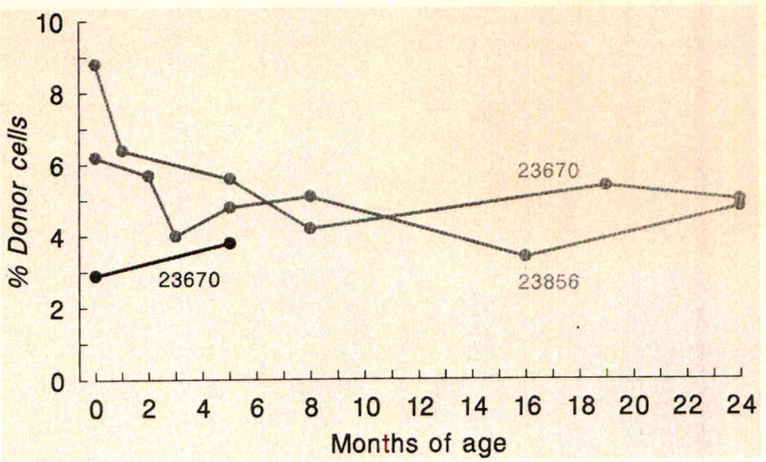

Fig. 9. Engraftment of peripheral blood leukocytes has persisted during 24 months of observation of three in utero hematopoietic stem cell transplant recipients.

in many countries fetal tissue is more readily available than adult cadaveric pancreas.[31]

Early studies in rodents of fetal pancreas grafts showed that fetal islet cells grew and functioned when transplanted to syngeneic animals and were capable, even in small quantities, of reversing alloxan-induced diabetes.[32, 33] In addition, they suggested that fetal islet allografts had a better survival than adult islets. However, more recent work[34] has confirmed that allografts of fetal pancreas are rejected within several weeks and that this rejection occurs despite treatment with cyclosporine. It appears, in fact, that late-gestation fetal islet tissue contains a large quantity of highly immunogenic lymphoid tissue.[35] It is possible that islet cells from earlier gestation would be less immunogenic, but it is unclear whether functional capacity would be adequate at very early gestational ages. It is known, for example, that early human fetal islet cells in culture do not respond to a glucose challenge before 25 weeks' gestation.[36] However, it is also clear that transplanted early fetal islet cells will grow, develop, and eventually function normally in a syngeneic or athymic host. One recent study documented normal glucose tolerance curves in alloxan-treated nude mice 6 to 8 weeks after transplantation of human fetal islet cells of 13 to 17 weeks' gestation.[37] Attempts have been made to decrease the immunogenicity of fetal islet cell grafts, by means of a number of different techniques. It was noted in mice that immunogenicity could be decreased by culturing the islet cells in media with a high concentration of oxygen.[38] Although results have been less impressive in the rat model,[39] this concept has undergone further investigation and the technique has been used in a number of clinical trials.[40] Others have attempted to decrease immunogenicity by decreasing the number of passenger lymphocytes in the graft. This can be done by exposure to ultraviolet radiation,[41] treatment with specific antibodies,[42] and passaging the islet cells through an interim host, usually the nude mouse.[43] The efficacy of these techniques in large animal and human systems has yet to be proved.

One further technique of interest is encapsulation of islet cells with a semipermeable membrane,[44] which allows glucose and insulin to pass but inhibits larger molecules such as immunoglobulins. This concept has great appeal, and initial results in animals have been encouraging.

Transplantation of fetal dopaminergic neurons

Parkinson's disease is a condition in which there is a failure of dopaminergic input from the substantia nigra to the striatum, resulting in progressive tremor, extrapyramidal signs, and hypokinesia. The disease is probably caused by degeneration of the dopamine-producing cells in the substantia nigra. The concept of cellular transplantation of dopamine-producing cells, with stereotaxic surgery, has opened an exciting new vista for the treatment of this disease and has stimulated a tremendous amount of experimental research over the past decade.

There were several problems with the idea from the outset. It is well known that adult neurons do not divide, and it appeared doubtful that these cells, even if they were to survive and proliferate, would establish the appropriate connections in the brain to function in the desired manner. The second problem was that of rejection. Despite the fact that the brain is relatively "privileged" immunologically,[45] it can clearly mount an immune response to foreign tissue.[46] The solution to both of these problems lay in the use of fetal tissue from very early gestation, which is less immunogenic and still has the ability to divide and establish neuronal connections.[47]

Initial experiments in rodents proved that cells taken from fetal brain, adrenal gland, or spinal cord would survive in an autologous recipient, would grow and

divide, and would function, even so far as to reverse symptoms in various models of parkinsonism.[48] These results have been duplicated in allogeneic transplants in nonhuman primates.[49] Even xenografts (mouse to rat, monkey to rat, and human to rat) have been shown to function and survive if the recipient is immunosuppressed with cyclosporine.[50] There is some evidence that rejection can be decreased and function improved by in vitro culturing of the cells before transplantation.[51]

Further studies with models of Parkinson's disease in nonhuman primates have confirmed the efficacy of transplanting fetal dopaminergic neuronal tissue. This has been done successfully by a number of investigators without immunosuppression and with relatively long-term effect.[52,53] It is interesting that preliminary human trials with autologous adrenal cells used as the donor tissue have been largely unsuccessful.[54] This is probably due to the inability of adult tissue to grow, divide, and function in a transplant situation. Clinical trials with human fetal tissue are under way,[55] and the results of these trials are awaited with great interest.

Transplantation of fetal liver cells

Transplantation of hepatocytes is an appealing alternative to orthotopic liver transplantation in patients with a hepatic enzyme deficiency such as ornithine transcarbamylase deficiency or a factor deficiency such as hemophilia, since they have otherwise normal liver. An additional advantage, unlike the procedure for whole organ transplantation, is that hepatocytes can be "banked" by cryopreservation until an appropriate donor is found. Finally, hepatocellular transplantation is minimally invasive and would not preclude orthotopic liver transplantation if it failed.

Fetal hepatocytes, although functionally immature, have been shown to be less immunogeneic than postnatal hepatocytes, evolving little or no immune response from the host.[55] The use of fetal hepatocytes in transplantation might have the advantage of reduced immunogenicity and a decreased need for immunosuppression. Thus the fetus may be not only the ideal donor of hepatocytes but also the ideal recipient.

Advances in prenatal diagnosis now make it possible to identify fetuses with heritable metabolic disorders and factor deficiencies as early in gestation as 8 to 10 weeks,[18] well before the onset of fetal immunocompetence. In utero hepatocellular transplantation could reconstitute the deficiency before any clinical manifestation of the disease and result in long-lasting tolerance of the host, without need for long-term immunosuppression. In utero hepatocellular transplantation is a potential therapy in diseases currently incurable except by orthotopic liver transplantation. Numerous questions that need to be addressed experimentally include: (1) What is the best technical approach, i.e., intraperitoneal infusion, umbilical vein infusion, or intraparenchymal injection? (2) What is the role of hepatotropic factors in engraftment of fetal hepatocytes? (3) Could induction of tolerance in the recipient be induced by pure hepatocellular transplantation or are hematopoietic stem cells required? Investigation of in utero hepatocellular transplantation in animals with long gestations will be essential to the assessment of feasibility and potential clinical applicability for treatment of hepatic enzyme deficiencies in man.

Ethical issues in the use of fetal tissue for transplantation

Tissue obtained from a deceased human fetus is entitled to the same dignity and respect accorded tissue obtained from a deceased adult. In itself, the use of fetal tissue is not ethically objectionable, but because it becomes available as a result of a mother's decision to end her pregnancy, a potential ethical dilemma is created. The possibility is raised that the use of fetal tissue might encourage abortion (or pregnancies) that would not have occurred otherwise.

Although legalized abortion remains a hotly debated, controversial issue, a consensus has been forming regarding the ethical use of fetal tissue in research and clinical transplantation. A National Institutes of Health panel recently released their recommendations affirming that use of fetal tissue is ethically unobjectionable as long as certain guidelines are followed.[56] The Committee on Ethics at Stanford University Medical Center similarly affirmed the ethical use of fetal tissue.[57]

To avoid potential ethical problems in the use of fetal tissue, mothers should not be allowed to benefit in any way from the use of fetal tissue they have elected to abort. This should include any compensation of expenses associated with the abortion. Similarly, the physicians performing abortions should not be allowed to benefit from the subsequent use of fetal tissue. Physicians may consciously or unconsciously influence a patient's decision to have an abortion if they have a direct interest in the use of fetal tissue. Some have suggested that to avoid any conflict of interest even academic incentives (e.g., coauthorship of publications or grant support) should be excluded from physicians performing abortions.[58] The mother should not be allowed to designate a recipient of fetal tissue as this also might influence a woman's decision to have an abortion. These guidelines help to ensure that a woman's decision to terminate a pregnancy is in no way influenced by the subsequent use of fetal tissue. Fetal tissue obtained under these ethical guidelines can be used for transplantation research or therapeutic interventions.

Comment

The fetus should be the ideal donor of hematopoietic stem cells for transplantation. During human gestation hematopoietic stem cells are first found in the yolk sac at about the fourth week of gestation. It is from

here that the liver (sixth week of gestation) and spleen (seventh week of gestation) are seeded. From about the fourteenth to the twentieth week of gestation, hematopoiesis finally switches to the bone marrow.[59] The bone marrow is seeded by the liver as the liver was seeded by the yolk sac. Therefore fetal liver should be an ideal source of hematopoietic stem cells that are primed to seed waiting bone marrow.[60] Like postnatal bone marrow hematopoietic stem cells, fetal liver hematopoietic stem cells are pluripotential and have the capacity to differentiate into a complete repertoire of erythroid, myeloid, thromboid, and lymphoid cell lines.[61, 62] Although hematopoietic stem cells from fetal liver may not be as efficient as postnatal bone marrow hematopoietic stem cells in terms of the number of colony-forming units seen when the same number of nucleated cells is injected,[63] fetal liver cells have the advantage of being primed and ready for hematogenous seeding of the recipient marrow.[59]

The most important advantage of fetal hematopoietic stem cells as donor material is that graft-versus-host disease may be ameliorated or avoided. If the fetal host is immunotolerant of a graft (see below), it follows that donor fetal hematopoietic stem cells should be immunotolerant of the recipient, because the lymphocytes that respond to specific foreign antigens are still "naive." Lethally irradiated mice reconstituted with allogeneic fetal stem cells do not develop graft-versus-host disease.[64-67] In humans, lymphocytes capable of causing graft-versus-host disease are detectable in the thymus by the fourteenth week of gestation but are not detected in the liver until the eighteenth to twentieth week of gestation.[60] These observations led clinicians doing postnatal bone marrow transplants to use fetal liver hematopoietic stem cells from donors who were between 8 and 14 weeks' gestation. Indeed, no instances of fatal graft-versus-host disease have occurred in human recipients of fetal liver hematopoietic stem cells >14 weeks' gestation.[68-70]

The fetus may be an ideal host for transplantation of hematopoietic stem cells, not only because of its ontologic readiness for engraftment before 20 weeks' gestation but also because the fetus in very early gestation is immunotolerant and permits foreign grafts without rejection. Sustained engraftment of allogenic cells in a recipient fetus is critically dependent on fetal immunologic tolerance of the graft. Fetal tolerance resulting in permanent chimerism has been documented to occur naturally in animal and human twins with shared placental circulation,[26, 27, 71, 72] and fetal tolerance has been demonstrated experimentally in several animal models.[28, 29, 73] Although transplantation immunity develops early in all mammals of long gestation, there is a period in early gestation when the fetus is uniquely tolerant of foreign antigen, but exactly when in gestation tolerance is lost is not known.[74] In the sheep fetus, prolonged survival of allogeneic skin grafts before 67 days' gestation has been demonstrated, while grafts placed after 77 days' gestation are rejected vigorously.[75-77] In a previous study we observed chimerism in three of five lambs transplanted at 85 to 105 days' gestation with allogeneic adult bone marrow cells, suggesting that even after the onset of immunocompetence the fetus is uniquely susceptible to tolerance induction.[78] These animals sustained chimerism but ultimately died of graft-versus-host disease. We then showed that using fetal liver hematopoietic stem cells rather than adult bone marrow cells and transplanting them earlier in gestation yielded sustained engraftment without evidence of either rejection or graft-versus-host disease.[30] This study provides strong support for the concept that the fetus is an ideal recipient, as well as an ideal donor for hematopoietic stem cell transplantation.

The concept of in utero transplantation of hematopoietic stem cells is so appealing that it has already been attempted clinically. Linch and Rodeck[79] reported transplanting maternal bone marrow hematopoietic stem cells (depleted of T cells, thought to cause graft-versus-host disease, by monoclonal antibody treatment) into an 18-week fetus with severe hemolytic anemia. The fetus survived after multiple standard intrauterine transfusions, but there was no evidence of engraftment after birth. This is not surprising for two reasons. Adult (maternal) bone marrow is not ideal as donor material, especially since attempts to reduce graft-versus-host disease by depleting T cells[80, 81] may decrease the chance of successful engraftment by removing T-cell hematopoietic factors. The attempted transplant may have been too late (18 weeks) to allow engraftment without rejection.[82, 83] Certainly other attempts will be made, but clinical application of this promising therapy desperately needs evaluation in an appropriately rigorous animal model.

From a practical standoint, fetus-to-fetus hematopoietic stem cells transplants may allow the use of allogeneic stem cell grafts from unmatched donors and possibly even pooled donor cells, thus obviating the need for human leukocyte antigen typing and search for a specific donor as is generally required for postnatal bone marrow transplantation. It also would remove the need for pretreatment with radiation and/or chemotherapy, as is necessary with immunocompetent recipients who have the capacity to reject an allogeneic graft.[3, 5, 15] Another reason for pretreatment of the postnatal recipient is to rid the bone marrow stroma of its occupant cells to make room for the implantation of injected hematopoietic stem cells.[3] In the period before the twentieth week, not only does the human fetus have a depleted stromal environment, but it is programmed for the reception of hematopoietic stem cells.[59] Fetal immunotolerance and stromal preparedness obviate the need for host preparation with chemotherapy

and/or irradiation, a significant disadvantage of postnatal bone marrow transplantation.

In summary, cellular transplantation may provide a means for replacing absent or defective cells without the need for a solid organ transplant. The fetus may be an ideal donor for these cells in several situations, because of its unique immunologic and functional attributes. By the same token, the fetus makes an ideal recipient for hematopoietic stem cells and, potentially, for many other cellular transplants. Experimental work with fetal hematopoietic stem cells, islet cells, and dopaminergic cells suggests that the fetus may soon play an important role in the field of cellular transplantation.

LETTERS TO THE EDITORS

Methotrexate treatment of tubal pregnancy

To the Editors: Stovall et al. (Stovall TG, Ling FW, Buster JE. Reproductive performance after methotrexate treatment of ectopic pregnancy. AM J OBSTET GYNECOL 1990;162:1620-4) made a worthwhile contribution to our knowledge of methotrexate treatment of tubal pregnancies.

The authors stated that the intrauterine pregnancy rate of 90.1% in their series is superior to the 49% to 70% rate for linear salpingostomy in a review by Vermesh.[1] These two groups may not be comparable, and the pregnancy rates seem to have different derivations. The salpingostomy group included patients with apparently more severe tubal damage (e.g., dilatation ≤6 cm for inclusion; ruptured fallopian tubes). The 90.1% pregnancy rate derived by Stovall et al. is intrauterine pregnancies per total conceptions. The pregnancy rates in the salpingostomy review are intrauterine pregnancies per total patients.

The authors note that the principal value of this approach is to bypass the risk, cost, and morbidity of surgical intervention. Because laparoscopy was performed on all subjects to establish the diagnosis, one might take the point of view that the principal morbidity of endoscopic salpingostomy was already incurred and considering the cost of methotrexate and related toxicity monitoring, endoscopic salpingostomy would be the least costly and least morbid approach.

Reply

To the Editors: We thank Dr. Bateman for his letter with regard to our article. He is correct in stating that the surgical series of Vermesh et al. and our series of medically treated patients may not be comparable in terms of future pregnancy outcome. Because of an aggressive screening program at our institution, patients with ectopic pregnancy are diagnosed earlier than those in the past. Thus the ectopic pregnancies are smaller and associated with less tubal distortion than are patients included in most surgical series or patients in our institution who require surgical therapy.

The favorable cost/benefit ratio of methotrexate to laparoscopic surgical therapy is arguable when laparoscopy is used to diagnose the ectopic pregnancy. To avoid laparoscopy, we developed and implemented a nonsurgical algorithm for the diagnosis of ectopic pregnancy and are able to diagnose as well as treat ectopic pregnancy without surgery.[1] On the other hand, one might surmise that even when laparoscopy is needed for diagnostic purposes, less tubal damage is ultimately done with medical therapy than if the tube is cut, cauterized, or lased. In addition, it should be remembered that if conservative surgery is undertaken at the time of laparoscopy, human chorionic gonadotropin titer monitoring is required after surgery to detect the 5% of patients who have persistent trophoblastic activity. The cost and effort of this follow-up must be factored in whether or not the patient requires additional surgery or methotrexate therapy.

In our article, the pregnancy rate is reported in two manners. First, 78.6% of patients attempting pregnancy were able to conceive, whereas 90.1% of patients who conceived had intrauterine pregnancies. The 78.6% is still superior to the 49% to 70% rate for linear salpingostomy reported in the review by Vermesh et al. Finally, we accrued over 35 pregnancies after methotrexate therapy. The intrauterine pregnancy rate is 88% with a recurrent ectopic rate of 12%.

Nonimmune hydrops in fetal Niemann-Pick disease

To the Editors: Meizner et al. recently ascribed a new cause to nonimmune hydrops fetalis—Niemann-Pick disease (Meizner I, Levy A, Carmi R, et al. Niemann-Pick disease associated with nonimmune hydrops fetalis. AM J OBSTET GYNECOL 1990;163:128-9). Niemann-Pick disease, both type A[1] and type C,[2] have previously been implicated in nonimmune hydrops fetalis, as have Wolman's disease,[3] Salla's disease,[4] and β-glucuronidase deficiency,[5,6] extending the list of lysosomal storage diseases that may cause hydrops.

Reply

To the Editors: We appreciate the interest of Dr. Vidgoff in our work. With reference to her letter we would like to point out the following:

Dr. Vidgoff states that Niemann-Pick disease, both type A and type C, have previously been implicated in nonimmune hydrops fetalis and gives two references to support her statement. Is that really so?

In the first article by Schoenfeld et al.[1] neither the term nor the entity nonimmune hydrops fetalis is mentioned. The article deals with placental findings associated with Niemann-Pick disease and does not indicate any of the features of hydrops fetalis. Prenatal ultrasonographic findings of nonimmune hydrops fetalis are not the subject of the article, which describes the ultrasonographic (placental only), biochemical, and histochemical aspects of four affected fetuses with Niemann-Pick disease.

The second article mentioned by Dr. Vidgoff is by Maconochie et al.,[2] who reported on isolated fetal ascites in two fetuses affected by Niemann-Pick disease. Again, neither the term nor the entity of nonimmune hydrops fetalis is mentioned in this case report. Fetal ascites was the only ultrasonographic and clinical finding reported. Does this sole finding indicate "a previous description" of nonimmune hydrops fetalis as suggested by Dr. Vidgoff? Where are other findings associated with nonimmune hydrops fetalis, such as hydrothorax and generalized edema?

The sonographer searches for the classic findings of skin thickening >5 mm, placental enlargement >5 cm, ascites, pleural effusion, pericardial effusion, and polyhydramnios. In some studies, ascites alone is considered diagnostic of nonimmune hydrops fetalis.[3] Other studies are purposely skewed to severe nonimmune hydrops fetalis, requiring serous effusions in two body cavities or a serous effusion in one body cavity in addition to anasarca for the diagnosis.[4] This lack of precision leads to variation in the cases included in series of nonimmune hydrops fetalis.

Although it is true that ascites can be seen in the hydropic state, when it occurs alone it is often from a local rather than a generalized condition. Ascites has often been noted to occur with urinary and intestinal tract obstruction.[5] Fetuses that display only ascites, unassociated with generalized hydrops, generally have a better prognosis and should be considered separately. We share what most authors believe, that the diagnosis of nonimmune hydrops fetalis should be reserved to more than one serous cavity effusion (ascites, pleural effusion, or pericardial effusion) or a serous effusion in conjunction with anasarca.[6,7]

Because nonimmune hydrops fetalis was not present in any of the articles suggested by Dr. Vidgoff and because ascites alone is not sufficient for diagnosis of nonimmune hydrops fetalis, our case in which the fetus had both ascites and pleural effusion is the first to show true nonimmune hydrops fetalis in association with Niemann-Pick disease.

Low-risk cesarean section prophylaxis issue still unsettled

To the Editors: We read with considerable interest the article by Ehrenkranz et al. (Ehrenkranz NJ, Blackwelder WC, Pfaff SJ. Infections complicating low-risk cesarean section in community hospitals: Efficacy of antimicrobial prophylaxis. Am J Obstet Gynecol 162:337-43). We agree that the study objectives are important, but believe that the study design fails to adequately address those objectives. The selection criteria for low-risk patients included both nonlaboring patients with intact membranes and laboring patients with membranes ruptured up to 12 hours. These selection criteria have effectively included both true low-risk patients and high-risk patients (as defined by Gilstrap and Cunningham[1]).

The efficacy of antibiotic prophylaxis is used by attending physicians (a listed objective) cannot be evaluated for clinical use when the antibiotic used is not stated. Which antibiotic(s) was used, how many doses were given, and whether one antibiotic was more (or less) effective than the others are critically important when evaluating overall prophylaxis efficacy. The conclusions stated by the authors assume that all antibiotic prophylaxis is equivalent in this setting, and the use of any antibiotic in any regimen is effective in low-risk cesarean section settings.

The authors state that "Antibiotics administered up to 24 hours before operation were regarded as having been given for the purpose of antimicrobial prophylaxis." We are unaware of any data that antibiotics administered 24 hours before surgery have any effect on postoperative infectious morbidity. Although the authors later define the term *timely prophylaxis*, what was the purpose of their original definition? Were those patients given timely prophylaxis in addition? If so,

were these patients considered with patients who did not receive the other extraneous doses of antibiotics in evaluation of infectious morbidity?

The authors stated that new manifestation of pyuria was a criterion for urinary tract infection, and that fever and purulent sputum was a criterion for lower respiratory infection. We believe that neither of these criteria is sufficient for their stated diagnosis.

Finally, the statement was made that the administration of antibiotics failed to result in serious diarrhea; however, they failed to mention two other important potential adverse effects of antibiotic administration—anaphylaxis and bacteriologic shifts in colonizing flora and resistance patterns. Gibbs et al.[2] have shown a significant decrease in low-virulence organisms with a concomitant increase in gram-negative facultative anaerobic organisms after antibiotic prophylaxis.[2] This must be considered when making the recommendation to administer antibiotics to more than 100,000 women annually. Although anaphylaxis is rare with β-lactams (about 1 in 10,000), the administration of antibiotics to an additional 165,000 women will likely result in some cases of anaphylaxis. Death has resulted from anaphylaxis as a result of prophylactic administration of antibiotics.[3]

In conclusion, we believe that study design in this paper cannot clearly identify an advantage of prophylactic administration of antibiotics to true low-risk patients undergoing cesarean section, and believe that the existing data suggest that the risks outweigh the benefits for this indication.

Reply

To the Editors: Pearlman et al. raised important points about our article.

Inherent infection risks are defined in untreated populations. Gilstrap and Cunningham[1] found 94.6% of untreated indigent women with membrane rupture >6 hours had infection after cesarean section. In our low-risk, untreated private patients, endometritis and wound infection totalled only 4.1%. Review of our case-control groups reveals 50% of both had no membrane rupture, and the proportions with rupture ≤6 and >6 hours were similar. In nonindigent women, membrane rupture durations ≤15 hours have not been associated with infection.[2-4]

Since 1970 symptomatic urinary tract infection criteria have included pyuria ≥10 white blood cell count.[5, 6] Probable lower respiratory tract infection is authoritatively defined as new fever, purulent sputum, and leukocytosis.[7] Inasmuch as concurrent leukocyte counts were frequently unavailable, we used the first two criteria. Use of additional criteria could not have increased our low infection rates.

In our cohort study, to seek any measureable prophylactic efficacy, we evaluated antibiotics administered up to 24 hours preoperatively. In the case-control study we collected extra information to explore whether timely prophylaxis (from 2 hours before to 4 hours after incision) might be efficacious.

We are mystified that Pearlman et al. "are unaware of any data that antibiotics administered 24 hours before surgery have any effect on postoperative infectious morbidity." Oral antibiotics administered only the day before bowel surgery are well known to prevent postoperative infections. These antibiotics numerically diminish enteric mucosal-associated bacteria below levels permitting operative site infection.[8] Systemically absorbed antimicrobial agents administered up to 24 hours before cesarean section might similarly diminish genital mucosal-associated bacteria—a potential cause of intrauterine contamination.[1]

Of 906 women (49%) in our cohort who received antibiotics prophylactically, over 60% received a first- or second-generation cephalosporin and 90% received one of these cephalosporins or a penicillin. We made no conclusion from our data about relative efficacies of different regimens.

Currently 50% of low-risk patients receive three or more antimicrobial doses. Martens, et al.[9] found one cephalosporin dose less likely to induce colonization by resistant bacteria than three. If 100% of patients receive one dose and both regimens are equally effective, a net reduction in antibiotic-resistant bacteria is entirely possible. We suggested three cefazolin doses on the basis of well-designed studies, but indicated that one-dose courses had potential annual savings of $9,400,000.

Finally, concern about anaphylaxis has been expressed. Up to 40% of hospitalized patients receive antimicrobial agents; however, documented cephalosporin-induced anaphylaxis is extremely rare. For previously unidentified anaphylaxis-susceptible women, an operating room is the safest place for such a rare occurrence, with life-support facilities immediately available. Cephalosporins administered only after cord-clamping pose no risk to infants.

In summary, we do not believe our Houston colleagues have offered a sufficiently strong rebuttal to the evidence from our study to alter the interpretations we have drawn.

Chlamydial infection and pregnancy outcome

To the Editors: Ryan et al. presented data on *Chlamydia trachomatis* infection and pregnancy outcome (Ryan GM, Abdella TN, McNeeley SG, Baselski VS, Drummond DE. *Chlamydia trachomatis* infection in pregnancy and effect of treatment on outcome. AM J OBSTET GYNECOL 1990;162:34-9). Of 2433 women who were chlamydia-positive at their first prenatal visit, 1323 (54%) were judged to have been adequately treated on the basis of a negative endocervical chlamydial culture after erythromycin therapy. A total of 9111 women from a similar demographic background were chlamydia-negative at their first prenatal visit. Neither group were recultured for chlamydial infection during the last trimester. The pregnancy outcome in 1110 chlamydia-positive women was documented. Details about intercurrent antibiotic therapy were not presented. Sexual partners were neither screened nor given antichlamydial therapy and thus provided a route for reinfection in those women who were treated.

The risk of chlamydial infection to infants born of infected mothers ranges from 50% to 70%.[1] Of 1083 live births to chlamydia-positive mothers, 541 to 812 infants were at risk of acquiring the infection. Furthermore, neonatal conjunctivitis could have developed in 20% to 50% of infected infants, whereas 30% of those with nasopharyngeal infection could have had a chlamydial pneumonia. Asymptomatic prolonged vaginal, rectal, and pharyngeal carriage have been reported in up to 15% of infants infected with chlamydia.[2] This could have serious medical, social, and legal implications inasmuch as culture-proved chlamydial infection is used as a possible indicator of child sexual abuse. However, no information was given as to whether these children were being followed up or recalled for therapy.

Postpartum endometritis has been reported in association with *Chlamydia trachomatis*, developing 2 to 3 weeks after delivery.[3] This can occur in 30% to 60% of women with untreated antepartum chlamydial infection. Tubal damage may be a complication. However, cases were not documented in this study.

The most effective way to prevent neonatal chlamydial infection and puerperal morbidity is to treat all chlamydia-positive pregnant women. Their partners should receive appropriate therapy. Tests of cure should be performed and rescreening in the last trimester should be offered to those women previously found to be infected. There are no ethical justifications for further studies on pregnancy outcome in untreated chlamydia-positive women in whom risks of maternal morbidity and neonatal infection are well known.

Reply

To the Editors: The letter from Forster, Estreich, and Hooi is in agreement with our basic contention that chlamydial infections during pregnancy do adversely impact the pregnancy outcome and that all chlamydia-positive pregnant women should be treated.

Another point raised in the letter was whether patients with a positive culture who are treated early in pregnancy should have another culture near term because reinfection can occur. We recently completed a study that shows that only 11.7% of women with previously treated *Chlamydia trachomatis* had positive cultures in labor. A more surprising finding was that 59% of those with positive chlamydia cultures in labor were associated with negative antenatal cultures at the time of their first prenatal visit. We concluded that in our population late pregnancy cultures would be useful in all patients, not just in those with previously positive cultures.

Subsequent treatment of children born to chlamydia-positive mothers was beyond the scope of the article as presented, but studies are under way in this regard.

Finally, we agree that on the basis of current knowledge it would not be justified to perform studies on untreated chlamydia-positive women; but at the time this study was begun between September 1, 1982, and January 1, 1984, several studies had indicated no relationship between a positive culture for chlamydia in pregnant women and premature rupture of the membranes, prematurity, or low birth weight. These studies were cited in our bibliography.

We thank the writers for their interest.

Budd-Chiari syndrome, obstetric complications, and antiphospholipid antibodies

To the Editors: Budd-Chiari syndrome[1-3] has been associated with the presence of antiphospholipid antibodies (lupus anticoagulants or anticardiolipin antibodies), in addition to better-known obstetric complications. Diagnosis of antiphospholipid antibodies would be important in evaluation of a hypercoagulable state in the case reported by Ilan et al. (Ilan Y, Oren R, Shouval D. Postpartum Budd-Chiari syndrome with prolonged hypercoagulability state. AM J OBSTET GYNECOL 1990;162:1164-5) of a woman with both Budd-Chiari syndrome and preeclampsia.

The diagnosis would have added to treatment options when anticoagulation alone failed to halt progressive thrombosis by suggesting the addition of immunosuppressive agents or intravenous immunoglobulin infusions.[4] In addition to tests for antiphospholipid antibodies and the lack of evidence for protein C deficiency mentioned (presumably normal levels of protein C), other studies for hereditary and acquired thrombotic disorders would also be an important part of evaluation in such cases.[5] Perhaps the authors would share this information with us so we can learn from this woman's unfortunate outcome.

Reply

To the Editors: We appreciate the comments by Dr. Cowchock with regard to our case report of postpartum Budd-Chiari syndrome with prolonged hypercoagulability state. Budd-Chiari syndrome is known to occur in association with many hypercoagulable states including polycythemia vera; paroxysmal nocturia; hemoglobinuria; tumors such as adrenal carcinoma, hypernephroma, and hepatomas; radiation; oral contraceptives; proteins S, C, and antithrombin deficiencies; and inferior vena cava webs.[1-5]

During the past few years, cases of Budd-Chiari syndrome were described in patients with anticardiolipin syndrome.[4] The association of Budd-Chiari syndrome with pregnancy was first described by Chiari almost 100 years ago[5] and since then other case reports have been published.[6] These cases were all considered to be associated with the hypercoagulable state that occurs post partum.

The patient described in our article was unusual in that her hypercoagulable state lasted for months after delivery. We tried to find a basic systemic disorder that would explain the prolonged hypercoagulable state. Despite extensive workups including negative anticardiolipin test results, normal protein C and S levels, and searches for other malignancies, no explanation for the hypercoagulable state could be found.

We think the most likely reason for the prolonged and uneventful course was postpartum deep vein thrombosis that later initiated a cascade of prolonged hypercoagulable state with extension of pelvic vein thrombosis along the inferior vena cava.

Was there really a difference with amnioinfusion?

To the Editors: Research data of Dr. Owens et al. (Owen J, Henson BV, Hauth JC. A propspective randomized study of saline solution amnioinfusion. AM J OBSTET GYNECOL 1990;162:1146-9) showing the apparent benefits of amnioinfusion is a different finding from our clinical experience.[1] The authors' rate of 19% postpartum endometritis in their control group is high. Perhaps it reflects the high rate of cesarean section in the controls.

Given that the treated and control groups had the same mean cord pH, I question the authors' impression about the apparent differences in fetal distress between the two groups.

In our hospital, amnioinfusion appears to be most effective for the fetal heart rate abnormalities that occur after artificial rupture of the membranes. I wonder whether the authors have also observed success in treating this iatrogenic fetal heart rate abnormality?

Robert C. Goodlin, MD

Reply

To the Editors: Dr. Goodlin's interest in our study is appreciated.

We performed a randomized controlled trial of amnioinfusion in 100 patients to determine its clinical utility in our population. Our article confirmed a trend toward a lower cesarean section rate for fetal distress as Nageotte[1] and Miyazaki[2] have previously reported.

As Dr. Goodlin correctly states, the incidence of cesarean delivery in our control population was higher than in the amnioinfusion group ($p = 0.2$). This may have partly accounted for the lower observed incidence of endometritis in the amnioinfusion patients. If the incidence of endometritis is stratified according to method of delivery, the following data emerge: of the 75 patients who underwent a vaginal delivery, 3 of 40 controls and none of 35 amnioinfusion patients had a postpartum infection. Similarly postcesarean endometritis developed in only one of 8 amnioinfusion patients compared with 8 of 17 control patients. Whereas neither of the stratified proportions are statistically significant at the $p = 0.05$ level, the trend, particularly in the postcesarean patients, is obvious. However, if amnioinfusion lowers the cesarean delivery rate, then it should have a favorable effect on the overall incidence of endometritis, which we demonstrated.

As stated in our conclusion, we would not expect a technique such as amnioinfusion to improve the cord pH with optimal labor management, the goal of which should be to effect delivery before fetal acidosis has occurred. Clearly the diagnosis of fetal distress is problematic and awaits more reliable and specific tests than a fetal monitor can offer.

Last, we have continued to use amnioinfusion at our institution, usually in the setting of persistant moderate to severe variable decelerations associated with labor in women with ruptured membranes. Although anecdotal, we continue to be impressed by the ability of this technique to correct these nonreassuring fetal heart rate patterns and permit progression to a vaginal delivery in many of these women.

Coagulation changes on natural estrogens

To the Editors: I would like to comment on an article that was published in a supplement to the American Journal of Obstetrics and Gynecology (Notelovitz M. Estrogen replacement therapy: Indications, contraindications, and agent selection. Am J Obstet Gynecol 1989;161:1832-41).

In the section on coagulation and thrombosis, the authors of the study that describes the increase of platelet aggregation in patients who take conjugated equine estrogens were Leon Poller, Jean Thomson, and Jean Coope, not Poller, Thompson, and Thomas as printed in reference 92 in the Journal.[1] The same authors had previously published a study of clotting changes in these patients that included increases in factors VII and X and shortening of the prothrombin time after 3 months of estrogen therapy.[2]

The negative study by Aylward et al. was not published as a refereed article but appeared as a letter in the *British Medical Journal.* A number of studies have shown that estrogen therapy may accelerate blood clotting, depending on the dose and the potency of the preparation. This is not unexpected inasmuch as endogenous estrogens have a similar effect, both during pregnancy and in the menstrual cycle.[3]

High CA 125 levels and spontaneous abortion

To the Editors: With great interest I read the article by Check et al. (Check JH, Nowroozi K, Vaze M, Wapner R, Seefried L. Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities. Am J Obstet Gynecol 1990;162:674-5) describing high CA 125 serum concentrations in three cases of spontaneous abortion. The authors hypothesized that high CA 125 levels would be predictive for an increased risk of chromosomal abnormalities and spontaneous abortions.

In a recent observation[1] we measured CA 125 serum levels exceeding 35 U/ml in 16 of 30 (53%) patients with nonviable pregnancies. In age-matched healthy pregnant women of the same gestational week, elevated CA 125 concentrations were found in 8 of 30 (27%). The incidence of elevated CA 125 serum levels in patients with intrauterine fetal death was significantly higher than that in women with viable conceptus ($p < 0.05$, the Wilcoxon U test). Given that intrauterine death is a result of a longer period of fetal impairment, it seems conceivable that CA 125 enters the maternal blood stream before fetal death.

Even though the lead time of the marker CA 125 for

fetal death is not yet defined, the hypothesis that CA 125 might be predictive for threatened abortions can be supported.

Amniotic endothelin increase during pregnancy

To the Editors: The ability of umbilical endothelial cells to synthesize endothelin in vitro,[1] the presence of endothelin immunoreactivity in umbilical vessels and fetal blood,[2] and the presence of endothelin-specific receptors in human placenta[3] and rat uterus[4] suggest that this potent vasoconstrictor and mitogenic peptide plays important roles in normal and pregnancy and delivery and those with pathologic findings. Endothelin immunoreactivity was shown to be increased in maternal blood during pregnancy[5] and high levels of endothelin immunoreactivity were reported in amniotic fluid at delivery.[6] We now report the kinetics of endothelin immunoreactivity increases in amniotic fluid during normal pregnancies and endothelin immunoreactivity levels in pregnancies complicated by intrauterine growth retardation.

Amniotic fluid (2.5 to 5 ml) was sampled by amniocentesis at two different gestational ages: 16.6 ± 1.6 weeks for prenatal diagnosis of genetic diseases ($n = 27$), and at 37.3 ± 2.2 weeks to verify fetal maturity before elective cesarean section ($n = 8$). All samples were obtained at room temperature (23° C) without anesthesia. Further processing of samples and endothelin detection were performed as previously described.[7]

Endothelin was already detectable in amniotic fluid (18.6 ± 8.9 pg/ml) at 16 weeks' gestation. Its levels increased during the third trimester (106.5 ± 30.9 pg/ml, $p < 0.001$). This value represents 20-fold the levels of endothelin immunoreactivity in normal human plasma (5 ± 1 pg/ml). In three cases complicated with intrauterine growth retardation endothelin immunoreactivity was higher (208.3 ± 109 pg/ml, gestational age 37.6 ± 2.5 weeks).

Although plasma levels of endothelin immunoreactivity are more elevated in pregnant than in nonpregnant women, they do not vary[5] or only slightly increase[6] with gestational age. The fivefold increase of amniotic endothelin immunoreactivity during the last trimester not only supports the hypothesis of a fetoplacental origin of the amniotic peptide but also suggests a controlled mechanism for its access to maternal blood all along the pregnancy. It could be speculated that the elevated concentrations of amniotic endothelin in the late phase of pregnancy may contribute to the uterine contractions and to the umbilical constriction at delivery.

The higher levels of amniotic endothelin immunoreactivity associated with intrauterine growth retardation also raise the possibility of an endothelin contribution to the pathogenesis of those gestational complications related with vasomotor control.

The University of Chicago, Center for Continuing Medical Education, 5841 South Maryland, Box 139, Chicago, IL 60637; (312) 702-1056

The Mount Sinai Medical Center of New York

Advanced Training in Geriatrics for BC/BE Gynecologists at The Mount Sinai Medical Center

The Mount Sinai Medical Center is offering a new intensive, one-year training program in geriatrics for BC/BE gynecologists, physiatrists, urologists and psychiatrists. The program is intended for academically-oriented clinical specialists seeking to focus their activities on those clinical, teaching and/or research aspects of their specialty that are of particular relevance to older age groups.

The training, coordinated by the Department of Geriatrics and Adult Development, will have didactic, clinical and research components: 40 percent of the time will be devoted to a core curriculum in geriatrics and gerontology; 40 percent will be devoted to scholarly activities in an area of geriatrics relevant to the trainee's basic specialty; and the remaining 20 percent will be spent in clinical practice in the trainee's basic specialty, with a geriatric orientation.

Candidates for training must, by the effective date of the award, be at a minimum BE in their respective clinical subspecialties and have strong interest in pursuing careers in an academic setting.

Interested individuals should direct applications and inquiries to: Richard L. Berkowitz, M.D., Chairman, Department of Obstetrics, Gynecology & Reproductive Sciences, The Mount Sinai Medical Center, One Gustave L. Levy Place, Box 1170, New York, N.Y. 10029-6574. Telephone: (212) 241-5681.

An Equal Opportunity Employer.

Are you responsible for faculty recruitment?

Academic Physician Services offers *more* than a classified advertisement.

- The Academic Physician is a **bi-monthly publication** listing available positions in academic medicine. It is circulated to 127,000 potential candidates including all academic physicians, post-doctorate fellows and senior residents.
- We have established a **national clearinghouse service** offering continuous position updates for academic physicians in every specialty. (Over 1,800 physicians seeking opportunities have requested information on available positions).
- We offer the **strongest minority recruitment effort available**. The Academic Physician communicates directly to every potential woman and minority candidate.

This is the most direct and cost effective approach to communicate your position to all candidates in academic medicine. To find out about our new fee schedule and how you may utilize this service, please call (916) 939-4242.

Join The Partnership of Choice

Southern California Permanente Medical Group (SCPMG) is recognized as the nation's largest and most respected physician-managed, multi-specialty medical group.

Our continued growth has created new opportunities for:

OBSTETRICIANS & GYNECOLOGISTS

You'll have a choice of professional environments ranging from a 250-bed community hospital to a major teaching facility in a number of prime Southern California locations. Our active practices require proficiency in modern ultrasound and surgical techniques.

CHIEF OF SERVICE

An excellent opportunity for an experienced OB/GYN practitioner to lead an established and growing practice at our Panorama City Medical Center. You'll be responsible for supervising 20 OB/GYN Physicians, a Perinatologist, 8 Certified Nurse Midwives and 4 Nurse Practitioners. This team of professionals will handle approximately 3000 deliveries per year.

SCPMG provides the freedom, technology and resources to focus on quality patient care and the collaborative support of knowledgeable colleagues. **We also provide a highly competitive salary, paid malpractice and predictable hours.**

MATERNAL-FETAL MEDICINE

The Allentown Hospital–Lehigh Valley Hospital Center, an 830-bed tertiary care center in eastern Pennsylvania, is seeking a physician to direct the maternal-fetal service (including Level II ultrasound and antenatal fetal diagnostic procedures) and provide leadership and medical education in maternal-fetal medicine. Applicants should be board-certified or active candidates for certification in maternal-fetal medicine.

TAH–LVHC sponsors a fully accredited OB/GYN Residency Program and is a clinical campus of Hahnemann University in Philadelphia, where the successful candidate will be eligible for faculty appointment. The hospital is a referral center for a population of close to one million people and is a Level III Perinatal Center; of over 3,300 deliveries performed last year, 42% were designated high-risk. The department is supported by a 20-bed Level III NICU and also provides a full range of services to women with subspecialists in both reproductive endocrinology and gynecologic oncology. (Our current maternal-fetal subspecialist, who is our department Chair, will be leaving at the end of the year.)

The hospital is located in Allentown, a prosperous and desirable area with excellent schools and diverse cultural and recreational opportunities, one hour north of Philadelphia and one and one-half hours west of New York City.

Please submit a curriculum vitae, in confidence, to: **Headley S. White, Jr., M.D., Sr. V.P. Medical and Academic Affairs, c/o HealthSearch, 50 College Drive, Suite 325, Allentown, PA 18104, (215) 778-7993.** Equal Opportunity Employer.

University of Ottawa • Faculty of Medicine

Chair of Obstetrics & Gynecology

The University of Ottawa invites applications for the position of Chairperson of the University Department of Obstetrics & Gynecology.

Applicants must be eligible to practice in Ontario and hold certification of the Royal College of Physicians and Surgeons of Canada in Obstetrics & Gynecology. The Faculty is seeking an individual with a track record of clinical and academic excellence, leadership skills and potential to develop a strong research program in Obstetrics & Gynecology.

The Department is responsible for directing both undergraduate teaching and postgraduate programs in Obstetrics & Gynecology in the Ottawa Civic Hospital and Ottawa General Hospital. The successful candidate will hold a joint appointment as Chair of the University Department of Obstetrics & Gynecology and Head of one of the affiliated teaching hospitals.

The Faculty is seeking an individual who will hold a fulltime University appointment. Salary and fringe benefits are commensurate with qualifications and experience, and are in accordance with existing scales at the University of Ottawa.

Priority will be given to Canadian citizens and permanent residents of Canada in accordance with Canadian immigration requirements. Employment equity is University policy.

A working knowledge of both English and French is desirable and a commitment to support bilingualism with the Faculty is essential.

Applicants are requested to forward their Curriculum Vitae and the names of three referees **prior to** February 15, 1991 to:

John F. Seely, M.D.
Dean, Faculty of Medicine
University of Ottawa
451 Smyth Road
Ottawa, Ontario
K1H 8M5

What are you waiting for?

SOUTHLAND SMC MEDICAL CLINIC

A tremendous opportunity awaits you in

Southern California.

We offer an extremely competitive compensation package coupled with the opportunity to enjoy an unprecedented lifestyle.

If you desire a rewarding and challenging practice in obstetrics and gynecology please contact us for immediate or future consideration.

Southland Medical Clinic

UTMB University of Texas Medical Branch Galveston, Texas

The Department of Obstetrics and Gynecology is currently recruiting for:

Gynecologic Oncologist

- Board eligibility or certification in gynecologic oncology required.
- Proven record of research and commitment to an academic career.
- Academic rank and salary commensurate with experience and qualifications.

Curriculum Vitae should be sent to:

Garland D. Anderson, M.D.
Jennie Sealy Smith Professor & Chairman
Department of Obstetrics & Gynecology
The University of Texas Medical Branch
Galveston, Texas 77550-2776

UTMB is an equal opportunity M/F/V/H affirmative action employer.
UTMB hires only individuals authorized to work in the United States.

OBSTETRICIAN GYNECOLOGIST

Western Massachusetts staff model Health Maintenance Organization is seeking two full-time, Board Certified/Board Eligible Obstetrician/Gynecologists to join our expert staff of five physicians and five midwives.

Our multi-specialty group practice employs 70 full-time physicians and provides care for a membership of over 65,000 patients in our modern suburban facilities. Inpatient care is provided at a 900-bed Tufts affiliated teaching hospital.

Attractive Pioneer Valley location with fine educational, cultural and recreational opportunities. Excellent salary and comprehensive benefit program. Please send curriculum vitae to: Oded Rencus, M.D., Chief of OB/GYN, 305 Bicentennial Highway, Springfield, MA 01118 or call (413) 594-3111.

PERINATAL ASSOCIATES OF NORTHERN CALIFORNIA

Are you a clinical perinatologist? We are three perinatologists and one geneticist-OB/GYN looking for one more perinatologist who: desires superior environment for patient care, in a private, modern, level 3 facility doing 6,000 deliveries a year with superior perinatal outcome; likes personal, direct hands-on patient care; needs PUBS, IUTxF, CVS and complicated pregnancies, level 2 ultrasound; demands partners, not superiors; wants to live in clean, warm, not humid, snow-free (but 60 minutes from skiing) Sacramento, California; feels one's family has priorities, and is committed to the private practice of medicine. If really interested call (916) 733-1755, extension 2773.

Hanns C. Haesslein, M.D.
Perinatal Associates
of Northern California
5301 F. Street
Sacramento, California 95819

NORTHERN CALIFORNIA

The Permanente Medical Group, a growing multispecialty group, is recruiting physicians in a variety of specialties for positions throughout our beautiful Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley.

Obstetrician/Gynecologist

BC/BE Obstetrician/Gynecologist sought to join small congenial clinic setting within established pre-paid multispecialty group. Practice consists of general obstetrics and gynecology, high risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser are welcomed. Association with resident staff and teaching opportunities available.

Kaiser Permanente offers competitive salaries and excellent benefits including full coverage malpractice insurance, medical, dental and group life insurance, vacation, educational leave and an excellent retirement program.

For more information, send CV to: Victor David, M.D., Chief, Obstetrics and Gynecology, The Permanente Medical Group, 901 Nevin Avenue, Richmond, CA 94801. EOE

KAISER PERMANENTE
Good People. Good Medicine.

The **Michael Reese Health Plan,** a large well-established HMO serving its members in 20 Health Centers throughout the Chicago Metro area, is seeking additional Board Certified/Eligible physicians in

Obstetrics Gynecology

Physicians with the Health Plan enjoy a full practice with modern facilities and equipment as well as opportunities for teaching. All specialty facilities available.

A highly-competitive salary and excellent benefits complement a rewarding practice and lifestyle.

Interested applicants should address inquiries to:

Alfred Kendrick, M.D.
Medical Affairs

Obstetrics and Gynecology Review Course

February 2-7, 1991 – Los Angeles

June 3-8 and November 25-30, 1991 – Chicago

Now, your course with case-list reviews and mock oral exams

OBJECTIVES

- Increase basic knowledge and clinical skills in ob-gyn.
- Assist residents and fellows to organize study
- Prepare exam candidates to pass their tests
- Provide practicing gynecologists with an update

METHODS

- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

TOPICS

Clinical Science
- Surgical Anatomy
- Embryology
- Radiology
- Genetics
- Teratology
- Anesthesiology
- Antibiotics

*"Accommodations were comfortable...."**

GOALS AND LOCATION: This course fc residents and practicing gynecologists is comprehensive review and update offere in the winter, spring and fall. The fa course is more clinically oriented. Hom study questions are sent upon registratio The course includes lectures with syllabu as well as an opportunity to purchase an ur limited number of optional extra one-or one sessions with faculty to review you case lists or do mock oral exams. Past pa ticipants recommend repeating the cours for half price immediately before exam The course hotel is chosen in competitiv bidding to achieve the best combination c bargain rates and excellent study enviror ment.

*"...and those little extras...."**

LOWEST AIR FARES: Please call tol free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 HOUR COURSE:

- Practicing Gynecologists: $75
- Residents and Fellows: $50
- Repeating course within 3 years: $37
- Case-list reviews and mock oral exams (half hour sessions): $ 7
- Private mock oral exams: $10
- Optional extra day Dec. 1 (more questions, answers and pathology lab): $15
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day
- A deposit of $50 will reserve your position

*"...home study material was extremely helpful."**

CANCELLATIONS: Refunds subject to $5 fee, will be made until the seminar begins.

*"...remarkably complete and pleasant."**

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Smooth Sailing!

ach white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet ontains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg noreth- ndrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

MPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information rovided with the product and therefore should not be used as the basis for prescribing the product. his summary was prepared by deleting from the complete prescribing information certain text, tables nd references. The physician should be thoroughly familiar with the complete prescribing information efore prescribing the product.

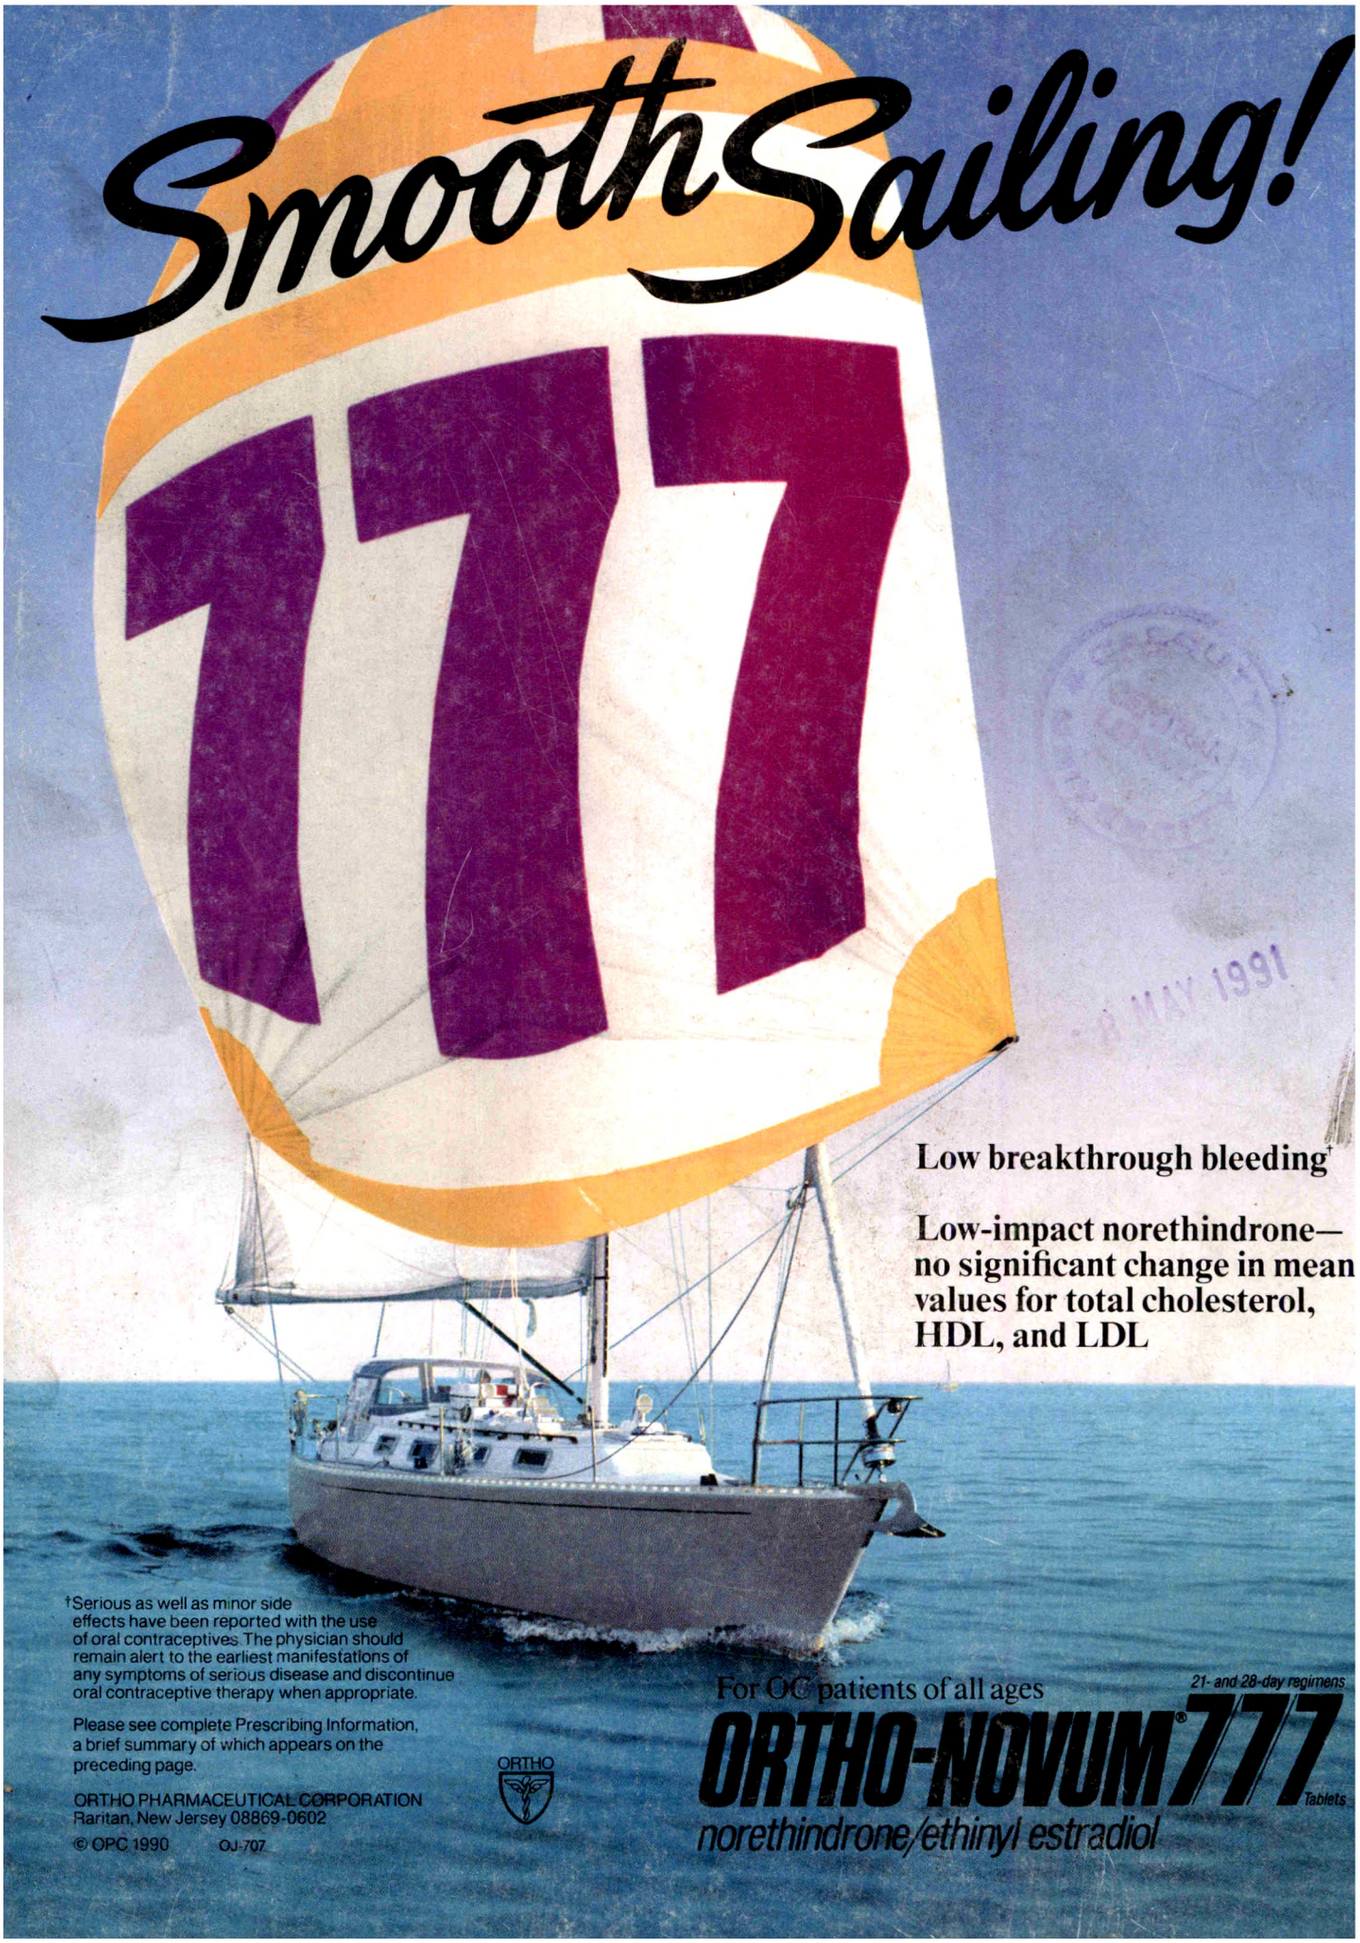
NDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

ONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following onditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophle- itis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected arcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-depen- lent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice vith prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including nyocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the isk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The isk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long erm use of the oral contraceptives with lower formulations of both estrogens and progestogens remains o be determined. Throughout this brief summary epidemiological studies reported are of two types: etrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**



ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH, BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thrombo-embolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners pre-scribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, con-firming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

Clinical Opinion

Epidemiologic characteristics of preterm delivery: Etiologic heterogeneity 467
David A. Savitz, PhD, Cheryl A. Blackmore, MPH, and John M. Thorp, MD
Chapel Hill, North Carolina

Causes of preterm delivery (preterm labor, premature rupture of the membranes, and medical complications) vary in frequency across populations, with implications for etiology and prevention.

Menstrual mythology and sources of information about menstruation 472
David C. Cumming, MB, ChB, Ceinwen E. Cumming, PhD, and Dianne K. Kieren, PhD
Edmonton, Alberta, Canada

Despite the availability of excellent educational material dealing with sexuality in general and menstruation in particular, conflict between formal and informal sources of information leads to persistence of menstrual mythology.

Clinical Articles

Inhibition of pulmonary surfactant function by meconium 477
David Moses, MD, Bruce A. Holm, PhD, Patricia Spitale, MD, Mingyao Liu, MD, and Goran Enhorning, MD
Buffalo, New York

Dilute, nonobstructive concentrations of meconiun inhibit pulmonary surfactant function in vitro in a manner that is dependent on the surfactant concentration.

The effects of iodoprophylaxis on thyroid size during pregnancy 482
Rossella Romano, MD, Emmanuele A. Jannini, MD, Mario Pepe, MD, Alessandro Grimaldi, MD, Michele Olivieri, MD, Patrizia Spennati, MD, Francesco Cappa, MD, and Massimino D'Armiento, MD
L'Aquila, Italy

Results of this study show the role of iodoprophylaxis in preventing an increase in thyroid volume during pregnancy in an area with moderate iodine deficiency.

Contents continued from page 5A

Investigation of placental circulations by color Doppler ultrasonography 486
Eric Jauniaux, MD, Davor Jurkovic, MD, Stuart Campbell, MD, Asim Kurjak, MD, and Jean Hustin, MD, PhD
London, England, Zagreb, Yugoslavia, and Loverval, Belgium

Color Doppler ultrasonography reliably identified fetal and maternal signals of the placental circulation in 30 pregnancies between 18 and 40 weeks' gestation.

Reduction of cardiovascular disease–related mortality among postmenopausal women who use hormones: Evidence from a national cohort 489
Pamela H. Wolf, DrPH, Jennifer H. Madans, PhD, Fanchon F. Finucane, MHS, Millicent Higgins, MD, and Joel C. Kleinman, PhD
Bethesda and Hyattsville, Maryland

Women who use postmenopausal hormones experience a 34% reduction in death caused by cardiovascular disease.

Endosalpingosis as a cause of chronic pelvic pain 495
Susan A. Davies, MD, and Victoria M. Maclin, MD
Chicago, Illinois

Endosalpingosis, ectopic oviduct epithelium, is discussed in the case report along with a summary of the histologic characteristics, differential diagnoses, and possible causes.

Transvaginal ultrasonographic definition of the central nervous system in the first and early second trimesters 497
Ilan E. Timor-Tritsch, MD, Ana Monteagudo, MD, and Wendy B. Warren, MD
New York, New York

Transvaginal ultrasonographic scanning in the late first trimester and early second trimester clearly delineates central nervous system and brain structures.

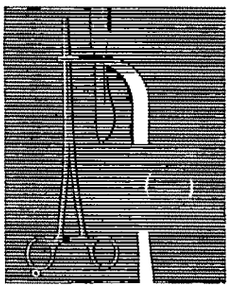
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.
Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.
In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).
The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.
If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.
Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.
Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.
In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.
CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.
As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.
Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.
Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.
Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.
When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

Females: 0.9 × value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Endodermal sinus tumor of the ovary during pregnancy: A case report 504
A.G.J. van der Zee, MD, H.W.A. de Bruijn, PhD, J. Bouma, MD, J.G. Aalders, MD, J.W. Oosterhuis, MD, and E.G.E. de Vries, MD
Groningen, The Netherlands

Chemotherapy was successfully postponed after surgical resection until a 24-year-old female with endodermal sinus tumor of the ovary during pregnancy was delivered of the infant.

Endothelial-derived relaxing factor released by endothelial cells of human umbilical vessels and its impairment in pregnancy-induced hypertension 507
Aldo Pinto, PhD, Raffaella Sorrentino, PhD, Paola Sorrentino, MD, Teresa Guerritore, MD, Lea Miranda, PhD, Augusto Biondi, MD, and Pasquale Martinelli, MD
Naples, Italy

Impaired endothelial-derived relaying factor could be involved in the altered regulation of blood pressure in pregnancy-induced hypertension; evidence is shown for a possible interference on the enzymatic pathway.

Prenatal records: A national survey of content 514
Mary D. Peoples-Sheps, DrPH, William D. Kalsbeek, PhD, Earl Siegel, MD, MPH, Cornelia Dewees, CNM, MN, Mary Rogers, MSN, and Robert Schwartz, MA
Chapel Hill, North Carolina

This national survey suggests that many prenatal records are not sufficiently detailed to perform the functions for which they are needed in the 1990s.

Reproductive factors and risk of endometrial cancer 522
Fabio Parazzini, MD, Carlo La Vecchia, MD, Eva Negri, ScD, Luigi Fedele, MD, and Fulvia Balotta, MD
Milan, Italy, and Lausanne, Switzerland

The relationship between reproductive factors and risk of endometrial cancer was analyzed in a case-control study conducted in the greater Milan area: Parous women had a 30% lower risk of the disease than nulliparous women, but there was no evidence of a decline in risk with increasing number of births and the protective effect of parity seemed to be greater in the short term after birth.

Cervical findings in rape victims 528
Laura Slaughter, MD, and Carl R.V. Brown, PhD
San Luis Obispo, California

We report two cases in which the colposcope was used to document cervical trauma after a sexual assault and we discuss its medical and forensic significance.

Continuous electrocardiographic monitoring in hypertensive crises in pregnancy 530
Datshana P. Naidoo, MD, Ismail Bhorat, MD, Jack Moodley, MD, Janardana K. Naidoo, MD, and Abdul S. Mitha, MD
Durban, South Africa

Serious ventricular arrhythmias occur frequently during hypertensive crises in pregnancy and may contribute to pulmonary edema and sudden death in these patients.

Umbilical artery blood flow velocity waveforms during variable decelerations of the fetal heart rate 534
Erich Weiss, MD, Thomas Hitschold, MD, and Peter Berle, MD
Wiesbaden, Federal Republic of Germany

Acute reverse flow of the umbilical arteries as well as an exclusive heart rate effect on flow velocity waveforms were found during variable decelerations of the fetal heart rate.

A case report of giant cell arteritis of the uterus and adnexa 540
P.R. Summers, MD, M.K. Biswas, MD, D.W. Boulware, MD, L. Green, MD, E.H. Herrera, MD, and A.G. O'Quinn, MD
New Orleans, Louisiana

The clinical significance of giant cell arteritis of the uterus is reviewed and a case report is presented.

Prospective analysis of sperm-oocyte fusion and reactive oxygen species generation as criteria for the diagnosis of infertility 542
R.J. Aitken, PhD, D.S. Irvine, MD, and F.C. Wu, MD
Edinburgh, Scotland

A prospective analysis of 139 untreated couples has revealed the significance of measurements of sperm-oocyte fusion and reactive oxygen species generation in the diagnosis of infertility.

The hemodynamic effects of intubation during nitroglycerin infusion in severe preeclampsia 551
Stephen Longmire, MD, Line Leduc, MD, Moncia M. Jones, MD, Joy L. Hawkins, MD, Thomas H. Joyce III, MD, and David B. Cotton, MD
Houston, Texas

Intravenous nitroglycerin was not effective in controlling the hypertension associated with intubation in a volume-expanded preeclamptic population.

Vasoactive intestinal polypeptide loses its ability to increase vaginal blood flow after menopause 556
Connie Palle, MD, Helle E. Bredkjaer, MD, Jan Fahrenkrug, PhD, and Bent Ottesen, PhD
Copenhagen, Denmark

In postmenopausal women the vasodilatory response in the vagina induced by vasoactive intestinal polypeptide may be dependent on the presence of sex-steroid hormones.

Analysis of antigen expression at multiple tumor sites in epithelial ovarian cancer 558
Stephen C. Rubin, MD, Connie L. Finstad, PhD, William J. Hoskins, MD, Diane Provencher, MD, Mark G. Federici, BS, Kenneth O. Lloyd, PhD, and John L. Lewis, Jr., MD
New York, New York

Cell surface antigen expression was consistent among primary and metastatic sites in epithelial ovarian cancer.

Contents

Reproducibility of the oral glucose tolerance test in pregnancy 564
Frederick E. Harlass, MD, Kim Brady, MD, and John A. Read, MD
Tacoma, Washington

The oral glucose tolerance test was reproducible in only 78% of pregnant patients and may need to be repeated if there are any abnormal values.

Steroid-responsive nephrotic syndrome with renal insufficiency in the first trimester of pregnancy 568
Luis G. Uribe, MD, Vashu D. Thakur, MD, and N. Kevin Krane, MD
New Orleans, Louisiana

Successful treatment of a woman with renal failure due to presumed minimal change nephropathy in the first trimester of pregnancy is presented.

Pharmacokinetics of acyclovir in the term human pregnancy and neonate 569
Lisa M. Frenkel, MD, Zane A. Brown, MD, Yvonne J. Bryson, MD, Lawrence Corey, MD, Jashvant D. Unadkat, PhD, Paul A. Hensleigh, MD, PhD, Ann M. Arvin, MD, Charles G. Prober, MD, and James D. Connor, MD
Los Angeles, Stanford, and San Diego, California, and Seattle, Washington

Acyclovir pharmacokinetics, late in the third trimester, is similar to that in nonpregnant adults, and although acyclovir accumulates in the amniotic fluid, neonatal and maternal levels at the time of delivery are similar.

Ovarian neoplasms and the risk of adnexal torsion 577
Marianne Sommerville, MD, David A. Grimes, MD, Paul P. Koonings, MD, and Keith Campbell, MD
Los Angeles, California

Adnexal torsion rarely involves cancer.

Laparoscopic pelvic lymphadenectomy in the staging of early carcinoma of the cervix 579
Denis Querleu, MD, Eric Leblanc, MD, and Bernard Castelain, MD
Roubaix and Lille, France

Laparoscopic surgery is adequate for dissection of external iliac, obturator, and internal iliac lymphatic areas in the pretherapeutic staging of early cervical carcinoma.

Umbilical cord ulceration and intestinal atresia: A new association? 582
Robert W. Bendon, MD, R. Wes Tyson, MD, Virginia J. Baldwin, MD, Kathryn A. Cashner, MD, Francis Mimouni, MD, and Menachem Miodovnik, MD
Cincinnati, Ohio, and Vancouver, British Columbia, Canada

Three cases of congenital intestinal atresia were associated with prenatal hemorrhage from unbilical cord ulceration.

Mechanisms of hemolysis and anemia associated with acute antepartum pyelonephritis 587
Susan M. Cox, MD, Paul Shelburne, MD, Ruble Mason, MT, ASCP, Stephen Guss, MS, and F. Gary Cunningham, MD
Dallas, Texas

Acute antepartum pyelonephritis is frequently complicated by anemia presumably because of the effects of endotoxin.

Fetal panting: Yet another response to the external vibratory acoustic stimulation test 591
David M. Sherer, MD, Jacques S. Abramowicz, MD, Mary Lou D'Amico, RN, Tamara Allen, BS, RDMS, and James R. Woods, Jr., MD
Rochester, New York

A rare case in which M-mode ultrasonography documented fetal panting at a rate of 119 movements per minute after external vibratory acoustic stimulation is presented.

The increased frequency of cervical dysplasia-neoplasia in women infected with the human immunodeficiency virus is related to the degree of immunosuppression 593
Axel Schäfer, MD, Wolfgang Friedmann, MD, Martin Mielke, MD, Bernhard Schwartländer, MD, and Meinrad A. Koch, MD
Berlin, Federal Republic of Germany

In women with human immunodeficiency virus infection, dysplasia of the uterine cervix is more frequent and related to the degree of functional impairment of lymphocytes.

Characterization of enzymes of catecholamine synthesis and metabolism in human fetal membranes at birth 599
Viviane Casimiri, PhD, Germaine Acker, PhD, Simone Parvez, PhD, Hasan Parvez, PhD, Lony Castro, MD, Calvin Hobel, MD, and Emile Papiernik, MD
Orsay and Clamart, France, and Los Angeles, California

The enzymes monoamine oxidase, catechol-O-methyltransferase, and phenylethanolamine-N-methyltransferase are present in the human amnion and chorion; the level of monoamine oxidase activity is greater in the chorion than in the amnion.

Pregnancy-related mortality in New York City, 1980 to 1984: Causes of death and associated risk factors 603
Carla J. Syverson, CNM, MN, MPH, Wendy Chavkin, MD, MPH, Hani K. Atrash, MD, MPH, Roger W. Rochat, MD, Elizabeth S. Sharp, CNM, DrPH, and Gail E. King, MD, MPH
Atlanta, Georgia, and New York, New York

Major causes of pregnancy-related death in New York City from 1980 to 1984 were ectopic pregnancy complications, embolism, intrapartum cardiac arrest, and hypertension that was induced or exacerbated by pregnancy.

Contents

Estrogen receptors in the external anal sphincter 609
Knut Haadem, MD, Lennart Ling, MD, PhD, Mårten Fernö, PhD, and Hans Graffner, MD, PhD
Helsingborg, Sweden

Estrogen receptors are present in the external anal sphincter in women, and at higher concentrations than those in men.

Prognostic factors in gestational trophoblastic tumors: A proposed new scoring system based on multivariate analysis 611
John R. Lurain, MD, Lisa A. Casanova, MD, David Scott Miller, MD, and Alfred W. Rademaker, PhD
Chicago, Illinois

Number of metastases, metastases to sites other than lung and vagina, and previous failed chemotherapy demonstrated independent significant effects on survival in patients with metastatic gestational choriocarcinoma.

Transient postpartum diabetes insipidus 616
A. Raziel, MD, T. Rosenberg, MD, P. Schreyer, MD, E. Caspi, MD, and Y. Gilboa, MD
Tel Aviv, Israel

Two cases of transient diabetes insipidus that first occurred immediately after delivery are described.

Postterm infants: Too big or too small? 619
Frances H. McLean, BScN, Mark E. Boyd, MD, Robert H. Usher, MD, and Michael S. Kramer, MD
Montreal, Quebec, Canada

When erroneous menstrual dates are eliminated with use of early ultrasonography, women who are delivered after term have large, proportionate (rather than small or scrawny) infants.

The biologic and social consequences of perinatal cocaine use in an inner-city population: Results of an anonymous cross-sectional study 625
Sandra McCalla, MD, Howard L. Minkoff, MD, Joseph Feldman, PhD, Isaac Delke, MD, Martin Salwin, MD, Gloria Valencia, MD, and Leonard Glass, MD
Brooklyn, New York

A finding of cocaine metabolites in urine of parturient women was associated with decreased use of prenatal care services, higher parity, lower birth weight, and more preterm births; recent use of cocaine was also associated with lower Apgar scores at 5 minutes that were not predicted by history.

The value of squamous cell carcinoma antigen in patients with locally advanced cervical cancer undergoing neoadjuvant chemotherapy 631
Giovanni Scambia, MD, Pierluigi Benedetti Panici, MD, Gabriela Baiocchi, MD, Mariangela Amoroso, MD, Elvira Foti, MD, Stefano Greggi, MD, and Salvatore Mancuso, MD
Rome, Italy

The serial measurement of squamous cell carcinoma antigen levels seems to be useful in monitoring response to neoadjuvant chemotherapy and in the detection of disease recurrence.

(Contents continued on page 14A)

Contents continued from page 13A

Neonatal complications at term as related to the degree of umbilical artery acidemia 637
Carey L. Winkler, MD, John C. Hauth, MD, J. Martin Tucker, MD, John Owen, MD, and Cynthia G. Brumfield, MD
Birmingham, Alabama

Neonatal complications as related to umbilical artery acidemia were present only when the umbilical artery pH was <7.00, a metabolic component was present, and both 1-minute and 5-minute Apgar scores were ≤3.

Urinary tract dilatation in pregnancy 642
Mark A. Brown, MD
Sydney, Australia

Massive dilatation of the right ureter and renal pelvis was monitored during pregnancy with serial ultrasonography and was shown to resolve within 2 days after delivery.

Current Development

Clinical implications of screening for cervical cancer under Medicare 644
Jeanne Mandelblatt, MD, Clyde Schechter, MD, Marianne Fahs, PhD, and Charlotte Muller, PhD
New York, New York

The natural history of cervical cancer in elderly women is reviewed to provide clinicians with the background necessary to implement screening programs under Medicare.

BASIC SCIENCE SECTION

Toxicities in rats with free versus liposomal encapsulated cisplatin 652
Ronald K. Potkul, MD, Javed Gondal, PhD, Pincas Bitterman, MD, Kenneth L. Dretchen, PhD, and Aquilur Rahman, PhD
Washington, D.C.

Liposomal encapsulation prevented the nephropathy and peritoneal fibrosis induced by cisplatin that was administered intraperitoneally in the Wistar rat.

Cocaine in pregnancy: The effect of maternal administration of cocaine on the maternal and fetal pituitary-adrenal axes 658
J.R. Owiny, PhD, M.T. Jones, PhD, D. Sadowsky, T. Myers, A. Massman, MD, and P.W. Nathanielsz, MD, PhD
Ithaca, New York

In sheep at term, maternal intravenous injection of cocaine resulted in transient fetal hypoxemia and increase in maternal and fetal plasma adrenocorticotropic hormone and cortisol concentration.

Contents

Human amniotic fluid modulation of collagenase production in cultured fibroblasts 664
Felipe Vadillo-Ortega, MD, PhD, Georgina González-Avila, MD, MSc, Carlos Villanueva-Diaz, MD, José Luis Bañales, BSc, Moisés Selman-Lama, MD, MSc, and Alberto Alvarado Durán, MD
Mexico City, Mexico

Term amniotic fluid contains chemical signals that enhance the degradation of fetal membrane extracellular matrix components.

Epidermal growth factor receptor expression in normal ovarian epithelium and ovarian cancer. I. Correlation of receptor expression with prognostic factors in patients with ovarian cancer 669
Andrew Berchuck, MD, Gustavo C. Rodriguez, MD, Ahmed Kamel, MD, Richard K. Dodge, MS, John T. Soper, MD, Daniel L. Clarke-Pearson, MD, and Robert C. Bast, Jr., MD
Durham, North Carolina

Expression of epidermal growth factor receptor is a poor prognostic factor in epithelial ovarian cancer.

Dose effects of antenatal corticosteroids for induction of lung maturation in preterm rabbits 675
Bannie L. Tabor, MD, Evelyn D. Rider, MD, Machiko Ikegami, MD, PhD, Alan H. Jobe, MD, PhD, and James F. Lewis, MD
Torrance, California

Lung maturation induced by antenatal corticosteroids does not exhibit a linear dose response and is independent of surfactant pool size.

Phospholipase C activity in microorganisms associated with reproductive tract infection 682
James A. McGregor, MDCM, David Lawellin, PhD, Amalia Franco-Buff, MA, and James K. Todd, MD
Denver, Colorado

Phospholipase C is produced by numerous cervicovaginal microflora and may be a virulence factor in reproductive tract infection.

The action of nitric oxide in the perfused human fetal-placental circulation 687
Leslie Myatt, PhD, Anthony Brewer, BS, and Diane E. Brockman, MS
Cincinnati, Ohio

Nitric oxide that is generated intracellularly vasodilates the preconstricted human fetal-placental circulation and may contribute to maintenance of resting vascular tone.

Effects of acute hypermagnesemia on the threshold for lidocaine-induced seizures in the rat 693
Won W. Choi, MD, David S. Warner, MD, Daniel J. Monahan, MD, and Michael M. Todd, MD
Iowa City, Iowa

Acutely hypermagnesemic male, female, and pregnant rats required the same plasma concentrations of lidocaine to produce electroencephalographic seizures as did normomagnesemic counterparts.

Index to advertisers on page 56A

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. SPECTRA 400™...
a new concept in OB

Enhances decision-making capability

Only the SPECTRA 400 display system acquires fetal and maternal HR and UA data from up to 20 bedside monitors, analyzes all data for normal and abnormal features, and alerts the staff of critical conditions on all displays—throughout the OB unit. This timely, accurate and accessible information provides reassurance of normal conditions and enables earlier, more informed decisions when abnormal conditions arise.

Improves quality of patient care

Immediate access to comprehensive patient information—including 12 minutes of continuous trend data as well as details of the trend analyses—allows staff the flexibility of attending to the needs of one patient while closely following the status of others.

Reduces liability risks

The unique capabilities of the SPECTRA 400 system help assure that critical conditions receive prompt attention—resulting in improved patient care and a greater peace of mind for both patient and hospital staff.

Increases personnel efficiency

With the extended surveillance and alert capability of the SPECTRA 400 system, displays may be located at the central nurses' station, at bedside and other locations. This allows ready access to data from each monitored patient and permits staff to focus attention on the most pressing situations. Thus, the system helps reduce the stress often associated with multiple-patient responsibility and helps increase the efficiency of the entire staff.

"Central Systems"

Unique inter-room surveillance and alert capability

A more cost-effective system

Modular in design, the SPECTRA 400 is available as a basic system (4-bed capacity) which can be easily expanded as needs require to accommodate up to 20 beds. Additionally, the system is designed to accept numerous future capabilities—including many computer-based functions which can further enhance patient care and administrative efficiency.

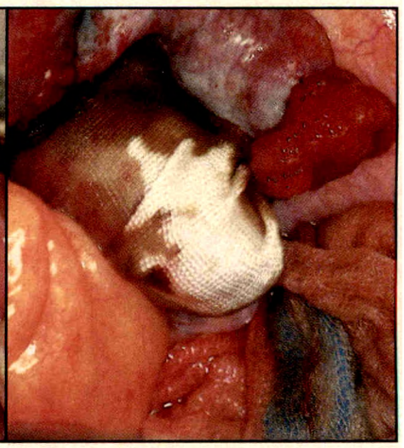
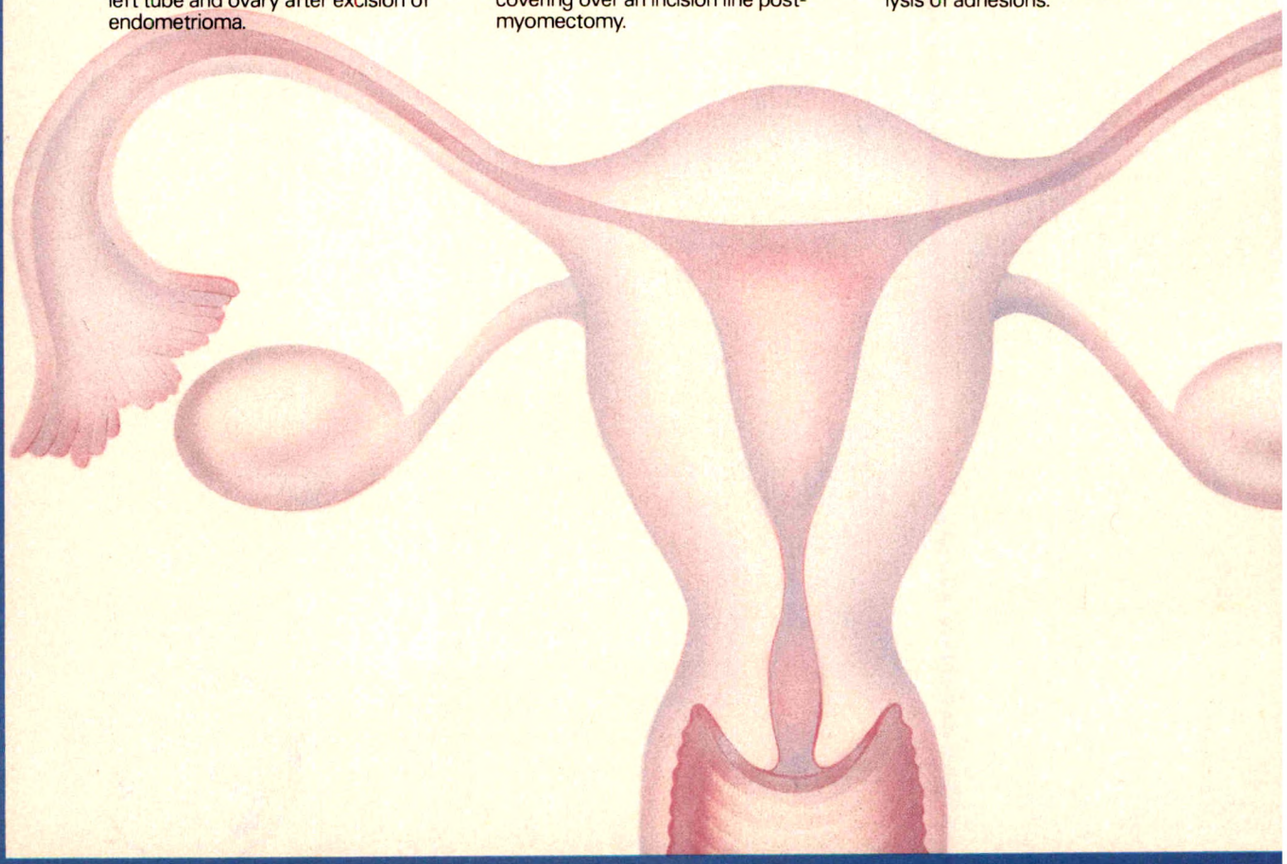
To significantly reduce adhesions...

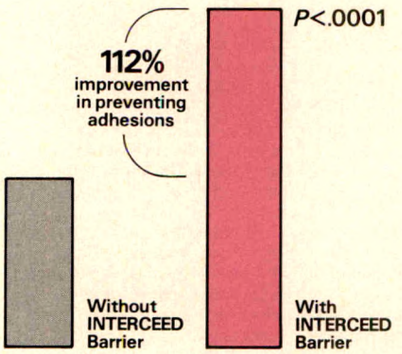


The first proven adhesion barrie



INTERCEED Barrier conforms to left tube and ovary after excision of endometrioma.

INTERCEED Barrier provides a protective covering over an incision line post-myomectomy.



INTERCEED Barrier covering ovary post-lysis of adhesions.

or gynecologic pelvic surgery

Twice as effective as state-of-the-art surgery alone[1]

n a controlled, multicenter study of 134 patients known to have formed bilateral pelvic adhesions previously, INTERCEED® (TC7) Absorbable Adhesion Barrier was more than *twice* as effective 51% vs 24%) in preventing recurrence of adhesions when compared with state-of-the-art surgical techniques alone.

The first surgical adjuvant specifically indicated to reduce postoperative adhesions

- No complications–material completely absorbed within 28 days
- Minimal tissue reaction–significantly less than other absorbable products
- Sutures not required–adheres well to serosal tissue
- Compatible with both laparotomy and laparoscopic techniques[2]

Clinically Proven

INTERCEED® (TC7)

Absorbable Adhesion Barrier

(OXIDIZED REGENERATED CELLULOSE)

Johnson & Johnson

MEDICAL INC.

Please see following page for brief summary of Prescribing Information.

Clinically Proven

INTERCEED®(TC7)

Absorbable Adhesion Barrier

(OXIDIZED REGENERATED CELLULOSE)

Brief Summary for INTERCEED® (TC7) Absorbable Adhesion Barrier (Oxidized Regenerated Cellulose). Before prescribing, please see full prescribing information.

INDICATIONS: INTERCEED Barrier is indicated as an adjuvant in gynecologic pelvic surgery for reducing the incidence of postoperative pelvic adhesions after hemostasis is achieved consistent with microsurgical principles.

CONTRAINDICATIONS: The use of INTERCEED Barrier is contraindicated in the presence of frank infection.

INTERCEED Barrier is not indicated as a hemostatic agent. Appropriate means of achieving hemostasis must be employed.

WARNINGS: INTERCEED Barrier must not be used in cases in which complete hemostasis has not been established. The effectiveness of INTERCEED Barrier is reduced when saturated with blood.

INTERCEED Barrier is supplied sterile. As the material is not compatible with autoclaving or ethylene oxide sterilization, INTERCEED Barrier must not be resterilized.

Although none have been reported, foreign body reactions may occur in some patients.

PRECAUTIONS: The safety and effectiveness of using INTERCEED Barrier in combination with other adhesion prevention treatment have not been clinically established.

Ectopic pregnancies have been associated with fertility surgery of the female reproductive tract. No adequate and well controlled studies have been conducted in women who become pregnant within the first month after exposure to INTERCEED Barrier. No data exist to establish the effect, if any, of INTERCEED Barrier on the occurrence of ectopic pregnancies. No teratogenic studies have been performed. Therefore, an avoidance of conception should be considered during the first complete menstrual cycle after use of INTERCEED Barrier. Care should be exercised in applying INTERCEED Barrier to a pelvic organ not to constrict or restrict it.

ADVERSE REACTIONS: To date, no adverse reactions have been reported attributable to the use of INTERCEED Barrier.

CAUTION: Federal law restricts this device to sale, distribution, or use by or on the order of a physician.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.
– Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than U.S. in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.
—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.
—Are numbered consecutively in the order they are cited in the text.
—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.
—Personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

"I was devastated when I found out I had genital herpes. What a relief when my doctor recommended a treatment program including Zovirax Ointment."

Zovirax® (acyclovir) Ointment 5% is an ideal complement to any treatment program for initial herpes genitalis. As clinical studies confirm, Zovirax Ointment 5% significantly lessens the duration of pain, shortens viral shedding, *and* speeds healing.[1-3]

Whenever the comfort of a topical antiviral medication is desired, prescribe Zovirax Ointment 5% for initial herpes genitalis. It suits her needs—just when she needs it most.

In initial herpes genitalis,

ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%
Antiviral Action... Proven Results

Please see brief summary of prescribing information on next page.

References: **1.** Lacey CJN, Meaden JD, Darville JM, et al. Topical acyclovir ointment in the treatment of genital herpes simplex virus infections. *Eur J Sex Trans Dis.* 1985;2:167-170. **2.** Thin RN, Nabarro JM, Parker JD, Fiddian AP. Topical acyclovir in the treatment of initial genital herpes. *Br J Vener Dis.* 1983;59:116-119. **3.** Corey L, Benedetti JK, Critchlow CW, et al. Double-blind controlled trial of topical acyclovir in genital herpes simplex virus infections. Acyclovir symposium. *Am J Med.* 1982;73:326-334.

ZOVIRAX®
(ACYCLOVIR) OINTMENT 5%

Before prescribing, please consult full package insert, a summary of which follows:

INDICATIONS AND USAGE: Zovirax (Acyclovir) Ointment 5% is indicated in the management of initial herpes genitalis and in limited nonlife-threatening mucocutaneous Herpes simplex virus infections in immunocompromised patients. In clinical trials of initial herpes genitalis, Zovirax Ointment 5% has shown a decrease in healing time and in some cases a decrease in duration of viral shedding and duration of pain. In studies in immunocompromised patients with mainly herpes labialis, there was a decrease in duration of viral shedding and a slight decrease in duration of pain.

By contrast, in studies of recurrent herpes genitalis and of herpes labialis in nonimmunocompromised patients, there was no evidence of clinical benefit; there was some decrease in duration of viral shedding.

Diagnosis: Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[1] Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases.

CONTRAINDICATIONS: Zovirax Ointment 5% is contraindicated for patients who develop hypersensitivity or chemical intolerance to the components of the formulation.

WARNINGS: Zovirax Ointment 5% is intended for cutaneous use only and should not be used in the eye.

PRECAUTIONS:

General: The recommended dosage, frequency of applications, and length of treatment should not be exceeded (see DOSAGE AND ADMINISTRATION). There exist no data which demonstrate that the use of Zovirax Ointment 5% will either prevent transmission of infection to other persons or prevent recurrent infections when applied in the absence of signs and symptoms. Zovirax Ointment 5% should not be used for the prevention of recurrent HSV infections. Although clinically significant viral resistance associated with the use of Zovirax Ointment 5% has not been observed, this possibility exists.

Drug Interactions: Clinical experience has identified no interactions resulting from topical or systemic administration of other drugs concomitantly with Zovirax Ointment 5%.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg/day given by gavage. These studies showed no statistically significant difference in the incidence of benign and malignant tumors produced in drug-treated as compared to control animals, nor did acyclovir induce the occurrence of tumors earlier in drug-treated animals as compared to controls. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive response for mutagenicity and chromosomal damage occurred, but only at concentrations at least 1000 times the plasma levels achieved in man following topical application.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day or in rats at subcutaneous doses up to 25 mg/kg/day. In rabbits given a high dose of acyclovir (50 mg/kg/day, s.c.), there was a statistically significant decrease in implantation efficiency.

Pregnancy: *Teratogenic Effects.* Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c. and i.v.) or in standard tests in the rat (50 mg/kg/day, s.c.). In a non-standard test in rats, fetal abnormalities, such as head and tail anomalies, were observed following subcutaneous administration of acyclovir at very high doses associated with toxicity to the maternal rat. The clinical relevance of these findings is uncertain.[2] There are no adequate and well-controlled studies in pregnant women. Acyclovir should not be used during pregnancy unless the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: Because ulcerated genital lesions are characteristically tender and sensitive to any contact or manipulation, patients may experience discomfort upon application of ointment. In the controlled clinical trials, mild pain (including transient burning and stinging) was reported by 103 (28.3%) of 364 patients treated with acyclovir and by 115 (31.1%) of 370 patients treated with placebo; treatment was discontinued in 2 of these patients. Other local reactions among acyclovir-treated patients included pruritus in 15 (4.1%), rash in 1 (0.3%) and vulvitis in 1 (0.3%). Among the placebo-treated patients, pruritus was reported by 17 (4.6%) and rash by 1 (0.3%).

In all studies, there was no significant difference between the drug and placebo group in the rate or type of reported adverse reactions nor were there any differences in abnormal clinical laboratory findings.

OVERDOSAGE: Overdosage by topical application of Zovirax Ointment 5% is unlikely because of limited transcutaneous absorption (see Clinical Pharmacology).

DOSAGE AND ADMINISTRATION: Apply sufficient quantity to adequately cover all lesions every 3 hours 6 times per day for 7 days. The dose size per application will vary depending upon the total lesion area but should approximate a one-half inch ribbon of ointment per 4 square inches of surface area. A finger cot or rubber glove should be used when applying Zovirax to prevent autoinoculation of other body sites and transmission of infection to other persons. **Therapy should be initiated as early as possible following onset of signs and symptoms.**

HOW SUPPLIED: Zovirax Ointment 5% is supplied in 15 g tubes (NDC 0081-0993-94) and 3 g tubes (NDC 0081-0993-41). Each gram contains 50 mg acyclovir in a polyethylene glycol base. Store at 15°-25°C (59°-77°F) in a dry place.

Mosby Year Book

Provide vital information to those who need it most . . . with article reprints from Mosby–Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby–Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:

- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information

Article reprints . . . another valuable service from Mosby–Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby–Year Book periodicals are available from the Publisher.

CLINICAL SECTION

Clinical Opinion

Epidemiologic characteristics of preterm delivery: Etiologic heterogeneity

David A. Savitz, PhD, Cheryl A. Blackmore, MPH, and John M. Thorp, MD

Chapel Hill, North Carolina

Preterm delivery (<37 weeks completed gestation) is known to result from diverse etiologic pathways, which can be grouped into idiopathic preterm labor, preterm premature rupture of the membranes, and medical complications. Data from publications providing sufficient detail to subdivide preterm delivery cases into these groups were tabulated. In spite of inconsistent terminology and incomplete reporting, patterns were identified. Black women have a markedly higher risk of preterm delivery, which is especially pronounced for preterm premature rupture of the membranes. Idiopathic preterm labor is predominant in lower-risk, white populations. These observations encourage consideration of subcategories of preterm delivery in studies of etiology and prevention. (AM J OBSTET GYNECOL 1991;164:467-71.)

Key words: Preterm delivery, preterm labor, premature rupture of the membranes, epidemiology

Early delivery is known to be related to increased infant morbidity and mortality, in both developed and developing countries.[1] Most studies of the causes and consequences of preterm delivery rely exclusively on gestational age of the infant, with little attention to the reasons for which the delivery occurred early. Studies that are based on vital records,[2, 3] for example, cannot evaluate specific causal pathways leading to early delivery since the information typically contained in birth certificates is inadequate for that purpose. Nonetheless, it is recognized that there are many different reasons for which the period of gestation may be undesirably curtailed.

The most common mechanisms involve idiopathic preterm labor or preterm premature rupture of the membranes, defined by whether labor or membrane rupture precipitates the sequence of events that culminate in delivery. In addition, there are numerous medical indications for early delivery such as fetal distress, maternal bleeding, or severe preeclampsia. The diversity of processes capable of resulting in preterm delivery would suggest that efforts to identify etiologic agents and ultimately methods of prevention consider each of those processes separately. If, for example, an exposure is related exclusively to idiopathic preterm labor, the observed association with preterm deliveries in the aggregate will be attenuated by a form of misclassification.[4] Thus studying more homogeneous entities should allow for the identification of quantitatively stronger determinants. Furthermore, preterm delivery prevention programs are often actually designed to recognize and intervene early if preterm labor begins, with success determined in part by the relative contribution of preterm labor to all preterm deliveries.[5-8] Finally, little attention has been paid to the possibility that the clinical consequences of prematurity could vary by the causal mechanism; i.e., whether the cause of prematurity or only the fact that it has occurred determines the sequelae for the infant.

Some investigators have addressed the heterogeneity

From the Department of Epidemiology, School of Public Health, and the Division of Maternal and Fetal Medicine, Department of Obstetrics and Gynecology, School of Medicine, University of North Carolina.

6/1/24106

in preterm delivery. Daikoku et al.[9] and Berkowitz[10] restricted their studies to noniatrogenic causes, principally preterm labor and preterm premature rupture of the membranes. In the context of a prematurity prevention program, Meis et al.[7] have provided the most sophisticated analysis of etiologic pathways among different racial and socioeconomic groups. A few other investigators, cited below, have provided sufficient detail to assess the relative or absolute frequency of preterm delivery resulting from different processes. As a prelude to studies of the specific entities of interest (e.g., preterm labor) and to appreciate the patterns of variation across populations, studies that permitted an assessment of patterns of preterm delivery were compiled for review.

Methods

Publications on preterm delivery that contained any data to subdivide cases by cause were sought. Varying definitions of preterm delivery were considered, with deviations from the standard definition of "<37 weeks completed gestation" noted, e.g., preterm among low-birth-weight infants. The following categories of preterm delivery were tabulated: (1) idiopathic preterm labor—labor starting without apparent reason before rupture of the membranes, resulting in preterm delivery; (2) preterm premature rupture of the membranes—spontaneous rupture of the fetal membranes at any time before the onset of labor resulting in preterm delivery; (3) iatrogenic—medically induced preterm delivery typically caused by conditions such as severe preeclampsia, maternal disease, or bleeding. Rarer causes such as trauma were not tabulated separately and were grouped with iatrogenic cases.

Characteristics of the study populations that were tabulated included the source [clinics, referral hospital(s), community census], geographic area, years, racial mix of patients, and socioeconomic characteristics of the patients. As available, the numerator and denominator for deriving the total preterm delivery proportion were obtained, with estimates of the subtypes of preterm delivery as a fraction of all cases and as a fraction of all births tabulated. Data often were not presented in the desired manner, but published results were reanalyzed, when possible, to derive the proportions of interest.

Results

The inconsistency in terminology across studies is striking. In some instances preterm births were restricted to those of a particular weight. Premature rupture of the membranes was often analyzed without stratification by gestational age. Articles that provided cross-classification of the data by several attributes were most informative, allowing reanalysis for the purposes of this review.

Estimates of the frequency of subtypes of preterm delivery were available from 16 populations, on the basis of 12 publications during the 1980s[7-18] (Table I). Most reports were based on case series from large referral hospitals, with one study of a geographically defined population[18] and one study subdivided into private and public clinics.[7] This simple division by provider yields useful information on social class and could easily have been incorporated into some of the other studies.

The studies were concentrated in the United States, with most covering urban areas, and two studies were from Scandinavia. Deliveries as far back as 1951 were included with the possibility of differences among studies as a result of secular trends in the causes of preterm delivery. Both white and black populations have been studied, as well as a range of social classes. For the purposes of describing the patterns sought in this paper, greater detail on the sources and social characteristics of patients would have been desirable. In many reports the source was defined only as the hospital, with no information on attributes of the population served.

Table II describes the patterns of preterm delivery across these populations. The study sizes vary markedly, ranging from 45[7] to 11,832[14] preterm cases. The overall risk of preterm delivery also varied markedly, from 4.4%[15] to 21.5%.[13] There is a clear pattern according to race: Black populations are at much higher risk of preterm delivery, with risks ranging from 10.8% to 17.8%. The highest rate (21.5%) was reported from the highly selected population that participated in the Collaborative Perinatal Project.[13] Lower rates were found in white and biracial populations, with some variation because of more restrictive definitions of preterm delivery (e.g., noniatrogenic cases,[10] preterm and low birth weight).[7, 10]

The distribution of subtypes of preterm delivery also varied across populations, with a tendency for low-risk populations to have the highest proportions of idiopathic preterm labor. Only the Finnish population[18] and a private clinic white population[7] had >50% of all preterm deliveries caused by preterm labor, with more than half of the noniatrogenic cases in Berkowitz's biracial population attributed to preterm labor.[10] The lowest proportions (under 30%) were reported in a public clinic black population[7] and from a referral hospital in St. Louis.[17]

Preterm premature rupture of the membranes varied from 7.1%[18] to 51.2%[7] of all preterm deliveries, with some of the range resulting from differing definitions of the total case group. Meis et al.[7] found that a greater proportion of preterm deliveries were due to preterm premature rupture of the membranes among blacks

and public (lower social class) patients as compared with whites and private (higher social class) patients, whereas this was not evident in the study of Johnson et al.[11] or in the literature overall. The medical causes of preterm delivery showed less variation. Proportions ranged only from 18.7% to 28.8%, with the exception of Arias and Tomich,[17] who included multiple gestations in this category, in contrast to other researchers who restricted their study populations to singleton births.

The absolute frequency of the subtypes of preterm delivery is a product of the risk of preterm delivery and the proportion associated with the specific cause. Preterm labor was most frequent in the (undefined) population served by The Johns Hopkins University Hospital,[9] a black population in Philadelphia,[8] and, somewhat surprisingly, in Finland.[18] Preterm premature rupture of the membranes showed a much clearer pattern of high risk for blacks, with risks of ≥5% observed in three studies focused on black populations,[7,8,11] as well as in the Collaborative Perinatal Project data[13] and in the population served by The Johns Hopkins University Hospital.[9] Notably low risks were found for white populations in Kansas,[15] North Carolina,[7] Finland,[18] and Sweden[16] and in the population of the Obstetrical Statistical Cooperative.[14] Unusually high frequencies of medically induced preterm deliveries were reported by Arias and Tomich[17] and Main et al.[8]

Comment

In spite of the well-recognized differences in the etiologic pathways resulting in preterm delivery, there has been little epidemiologic research to discriminate among them. To our knowledge, there are no studies focused on identifying risk factors for case groups defined by the mechanism of preterm delivery. In some studies of preterm delivery or even low birth weight, there would be the opportunity to assess determinants of case subgroups if researchers organized the available data appropriately.

Some studies of etiology have focused on specific associations, e.g., sexually transmitted diseases and premature rupture of the membranes.[19] However, most studies that address causes of preterm delivery do so without separating causal pathways.[20,21] The data summarized here suggest that there may be different risks for the different pathways of preterm delivery on the basis of racial and socioeconomic differences. The overall pattern reported by Meis et al.[7] is corroborated to some extent in other studies. White patients and those of higher social classes tend to have proportionately greater numbers of cases of preterm labor whereas

black patients and those of lower social classes tend to have more instances of premature rupture of the membranes. Given the overall higher risk of preterm delivery among black women, the absolute (as opposed to proportional) increase of premature rupture of the membranes is more notable.

These suggestions of heterogeneity encourage studies designed to elucidate the causes and assess the preventability of specific pathways for preterm delivery. Etiologic studies focused on homogeneous end points are much more likely to yield strong associations than are studies of heterogeneous end points. Nonetheless, it is possible that some of the apparently diverse pathways through which preterm delivery occurs may actually be manifestations of the same underlying pathologic condition. For example, certain infections appear to affect both preterm labor and preterm premature rupture of membranes.[22, 23] Only by disaggregating the cases into subgroups can that possibility be addressed.

The intense interest in preterm delivery prevention programs provides another strong incentive to evaluate more thoroughly the potential benefits of such interventions. These programs are largely based on identifying and responding to early signs of preterm labor,[7, 8] so that their success is determined in part by the extent to which preterm labor is the dominant cause of preterm delivery. Other obstetric practices and interventions such as routine vaginal examination are also under scrutiny for their potential beneficial or adverse consequences on the risk of preterm premature rup-

ture of the membranes.[24] In this case there may be a tradeoff in the risks and benefits with a potential advantage for detecting and treating cervical incompetence and a potential risk of introducing infection and precipitating membrane rupture or labor. The relative frequency of those possible outcomes must be considered in drawing conclusions, with the overall balance dependent in part on the characteristics of the population under study.

In spite of the limited quantity and quality of information on subtypes of preterm delivery, these results encourage further research. Investigators need to define more carefully the outcomes of interest in studies of both cause and interventions. Dividing preterm delivery into more homogeneous and thus tractable components is probably essential to progress toward understanding and prevention of this common problem.

We thank Dr. Watson Bowes for sharing his thoughts on this issue and reviewing the manuscript.

Addendum in proof

A recent article reports on a study focused on the cause of preterm premature rupture of the membranes (Harger JH, Hsing AW, Tuomala RE, et al. Risk factors for preterm premature rupture of fetal membranes: a multicenter case-control study. AM J OBSTET GYNECOL 1990;163:130-7).

Menstrual mythology and sources of information about menstruation

David C. Cumming, MB, ChB, Ceinwen E. Cumming, PhD, and Dianne K. Kieren, PhD
Edmonton, Alberta, Canada

Surveys suggest that, despite extensive scientific knowledge of the biologic rhythms and physical changes associated with reproduction and despite the availability of excellent educational material about sexuality including menstruation, young peoples' knowledge of reproductive physiology is inadequate. Superstitions, illogical beliefs, and misinterpretations are more common than accurate understanding. The present article reviews menstrual mythology and describes sources of information for young people. Family and specialist physicians as well as educators in school or in the community need to recognize the limitations of the present methods of sexuality education, must realize that understanding of reproductive processes may be very incomplete, and should be prepared to work cooperatively with informal sources of information (peers, parents, and commercial companies). In addition, menstrual education needs to move away from the focus on hygienic management to that of healthy sexuality and acceptance of self. (AM J OBSTET GYNECOL 1991;164:472-6.)

Key words: Menstruation, education, physician's role

Formal teaching of reproductive physiology and sexuality to young people involves more than the provision of facts; it must be provided within a clear understanding of the social and physical developmental needs of young people as well as the sociologic, ethical, moral, and religious contexts within which these needs are met. Information about reproductive function and sexuality is available to young people from a number of formal and informal sources. The ability to deal with the problems and misconceptions of menstruation requires an understanding of the ways in which sexuality information is provided to young people by formal educational sources and from commercial companies, parents, and peers.

Physicians learn reproductive physiology in what it is hoped are optimal circumstances and therefore may not be aware that the quality of information available to young people is variable and leads to the persistence of menstrual mythology. We have a special interest in promoting our patients' understanding of normal reproductive physiology, because women with accurate knowledge are less likely to misinterpret the significance of symptoms and more likely to be aware of when events in the menstrual cycle are abnormal. We are formal educators in the sense of knowledge, but our opportunities to educate are informal and we use the "teachable moment." Physicians are criticized because of a perceived discomfort in discussing sexuality and because of problems of application and interpretation of our factual knowledge within a human interpersonal context.

Our purpose in this article is to review myths and misinterpretations related to menstruation, sources of information currently available for menstrual education, and the implications for physicians and others involved in menstrual education programs in family, school, and community contexts. By understanding and supporting efforts to provide a high standard of education in reproduction and sexuality, we may improve the quality of life for our patients and diminish functional reproductive problems.

Myths, popular beliefs, and attitudes toward menarche and menstruation

Menarche has little intrinsic endocrine significance inasmuch as it is neither the beginning nor the end of reproductive maturation, but it does symbolize a stage of maturity characterized by preparedness of the young woman's body for increased sexual responsiveness and a clearer sex role identification, and opens up consideration of possible future roles, for example, sexual partner and mother. One might expect that menarche would be positively received by young women as it provides an unequivocal indication that development is unfolding as it should, but both positive and negative responses have been described. On the positive side, menarche leads to clearer expression of a girl's body image and a greater acceptance of womanhood.[1,2] More negative responses such as increased shame, fear, anxiety, and depression have also been noted. The manner

in which a girl learns about menstruation and its associated changes may have an impact on her response to the event and her acceptance of herself as a woman.[3]

The menstruating woman of biblical times was considered unclean and profane,[4] a belief that persists. Until quite recently, men often regarded her as "disgusting."[4] Young girls soon learn that menstruation is not to be discussed in public.[5] Despite greater physiological knowledge, the attitude toward menstruation as the "curse" is overwhelmingly negative and a source of embarassment to be concealed. Even today it is often assumed that physicians will not conduct a pelvic examination during menstruation.

Several studies document the limited knowledge young women have about menstruation. The composition and normal volume of menstrual flow was not known and a quarter believed that the flow rids the body of wastes.[4] Whereas 74% of the respondents knew that ovulation referred to ovum release, 61% had no knowledge of when ovulation actually occurred in the menstrual cycle and 56% did not know when pregnancy was likely to occur, findings with implications for both fertility and contraception. Many young people still believe that pregnancy cannot occur at first intercourse.[6]

Old wives' tales persist. Many young women believe that they should avoid cold, heat, bathing, swimming, and exercise during menstruation.[4,6] During the 1960s there was considerable debate in education literature over the advantages and disadvantages of excusing girls from physical education classes during menstruation. A tradition developed that menstruation was globally normal and should not interfere with any physical education or other program. A long-term exercise program does help to reduce perimenstrual symptoms and physical activity during menstruation need not be avoided by the majority. However, young women during an episode of painful menstrual cramping could end up feeling that their experience is being negated by inappropriately vigorous encouragement to participate.

There are inaccurate beliefs about affective state and cognitive processing during menstruation. Of the 1034 respondents in the North American study reported by McNab,[6] 87% believed that women are particularly emotional while menstruating. A third of respondents believed that menstruation affects a woman's ability to think. In another study, 75% of male college students and a surprising 32% of female college students believed the same thing.[7] Of 1034 young men and women over the age of 14 years, 25% believed tht women could not function normally at work in the premenstruum.[6] Most women experience no significant cognitive or affective changes premenstrually and can perform any of their life functions in a normal fashion during the premenstruum.[8,9] Young men and women both attribute negative emotions to biologic events (e.g., those of the menstrual cycle) and positive feelings to life events.[10] Negative expectations about menstruation develop even before puberty.[11]

However, not all findings are negative. Young women from higher socioeconomic backgrounds are more likely to possess more accurate knowledge about menstruation.[4] Young college students accepted menstruation rather routinely,[12] which suggests that appropriate education could eliminate many of the negative expectations of menstruation and perhaps many dysfunctional symptoms.

It is important that physicians be aware that young women may have a limited understanding of the biologic and physical changes that are occurring and be prepared to validate experiences and guide the educational process when this is appropriate. Physicians may also harbor negative attitudes and beliefs about menstruation and should take care not to add to the patient's impression.

Sources of information

Education about menstruation ideally should be just one topic in a comprehensive, lifelong process of sexuality education; it should be provided before puberty and build on a base of sexuality education provided by parents early in a child's life. Sexuality education should begin at home and continue as reproductive status changes over the life span. Before puberty, menstrual education is a natural entrée to informed discussion of sexual development and of the entire reproductive process including physical, social, and psychological aspects of coitus, conception, and birth. The actual situation, with respect to menstrual education as one part of sexuality education, differs from what is ideal. Even today many young women are not prepared for menarche. For others, education about the hygienic aspects of menstruation is the only aspect of sexuality education that they will receive.

Young girls receive information about menarche and menstruation from a wide variety of sources: parents, peers, teachers, medical personnel, commercial materials, television, and other media. These sources not only vary in quality of information provided but also in the value young girls give them as a potential information source. Whereas there is still controversy over sex education, North Americans overwhelmingly believe that both parents and schools should be involved in the sex education process.[13] However, it appears that it is one thing to believe that home and school should be involved and another to accomplish it. Both young persons and parents agree that many fewer parents provide sex education than those who believe that they should provide it.[13-16] Peers have a strong influence on adolescents' sexuality education.[13,16] Schools are much

less influential because comprehensive programs are conspicuously absent in many communities.

Concern may be expressed not only about the effectiveness of the sources of information but also the affective tone with which it is transmitted, particularly with respect to perpetuating the negative views of menstruation. Parents often have difficulty teaching their children about sexual matters such as menstruation. It is not uncommon for parents to feel embarrassed as well as unprepared to carry out this task effectively. Parent's lack of accurate information will perpetuate myths that they acquired.

Physicians generally have had no instruction on how to teach reproductive information to others who are not medically trained. Most learn from doing and may well not be as effective as they would wish to be. We usually are little involved in the formal education process as it relates to reproduction and menstruation. Despite the time constraints and difficulty of communication with teenage and preteenage patients, the physician who deals with young women should facilitate and be prepared to be involved.

Two key objectives should guide physicians who respond to young women seeking information about menarche and menstruation: (1) to provide accurate information about the nature of bodily functions and their relationship to other aspects of reproduction (sexual responsiveness, reproduction) and (2) to facilitate the development of positive attitudes in young women about their own sexuality. Closed communication leading to the persistence of myths and mistaken impressions associated with menstruation can prevent the achievement of the first objective. Encouragement of young women to see menstruation as a monthly physical and emotional crisis rather than a positive, normal event may interfere with the achievement of the second objective.

School programs have suffered from similar problems. The mandate for schools to teach about sexuality is far from clear. Like physicians, most teachers have not been formally prepared to teach sexuality and therefore must depend on in-service education for their personal preparation. When school education programs have been implemented, there has been a high dependence on the education materials provided by commercial paper product companies that sell sanitary products. Films are the most widely used teaching aid: an estimated 93 million women have seen the animated film *The Story of Menstruation* since 1973. Booklets produced by paper companies are the second most widely used resource.

Because similar materials may be available through physicians, we should be aware of the kind of information provided by the commercial sources, whose content is very much influenced by analyses of the intended consumer markets. The information is often ritualistic and rule bound, for example, specifying how a girl should feel rather than facilitating her self exploration. The materials are not adequate as a comprehensive educational resource because of vagueness in purpose and language; the cold, clinical presentation of body diagrams do not accurately present the systemic character of the reproductive system; there is denial of unpleasant body feelings or sensations and emphasis on hygiene used so that menstruation can be concealed. Whereas they present a systematic idea of how to manage this natural body function in a sanitary, hygienic and "dainty" manner, they do not facilitate the exploration of the range of feelings (e.g., sensual, fearful, anxious, happy) that may accompany the arrival of puberty. The emphasis on independence and giving the facts and information on products has implications as well for limiting parent-daughter communication. The nature of the materials written for mothers of normal girls discouraged ongoing open communication between parent and child about the girl's affective responses to menstruation or other sexuality issues. In contrast, the materials written for mothers of retarded girls not only gave more concrete examples about the event but also encouraged ongoing and open communication. It may be concluded that an unrealistic, adaptive rather than realistic and dynamic developmental model is presented to the young girl to incorporate this change into her life.

Three patient education pamphlets on reproductive matters are published by the American College of Obstetricians and Gynecologists (600 Maryland Avenue, SW, Suite 300 East, Washington, DC), two directed to teenagers (*Growing up* and *Being a teenager: you and your sexuality*) and one for parents *(Teaching your children about sexuality)*. The pamphlet for parents provides understanding of the difficulties that parents face in teaching their children but the tone is generally too philosophical with few concrete suggestions about breaking the ice. *Growing up* focuses on hygienic management with too little comment on the concrete aspects of the period and the often mixed personal feelings. *Growing up* would benefit from the approach of *Being a teenager: you and your sexuality* in which the tone is positive and covers sexuality, not mechanics. However, it does not deal with menstruation.

Newer books about the menstrual cycle have provided a much broader focus on sexuality. These include *Menstruation: Just plain talk* by A. Nourse,[17] *Every girl* by H. Doan and J. Morse,[18] *Period: A book about menstruation* by Gardner-Loulan, Lopez, and Quackenbush,[19] and *What's happening to me?* by P. Mayle.[20] They were written with the objectives of helping the girl to understand the body changes associated with menstruation and how this process might be managed but, more impor-

tant, they focus on development of a good body and self-image and a feeling of satisfaction with being a woman. The books do not play down the natural, within-gender variabilities of body functioning with respect to menstruation and they deal realistically and accurately with the problems that women have suggested they experience with menstruation.

Informal sources such as prime-time television programs and advertisements may convey attitudes about sexuality that we may not wish young people to assume.[21] Certainly, this is relevant to menstrual education inasmuch as advertisements for menstrual products on television and in the media in general tend to convey the attitude that managing this body event is a monthly crisis of hygiene.

It is in our interests as physicians to become involved in the debate over sexuality education and to review standards of the sources of information. Information that after review is considered helpful can be recommended. It is clear from the attitudes of well-educated young women that an educational process can lead to healthier attitudes toward reproductive function and reduce many of the minor problems that are overtly or covertly troublesome. However, physicians should not see the task of sexuality education as merely information exchange or delegate the provision of information to others but be prepared to integrate other sources into their patient management. The provision of reading materials should be viewed as a complement to direct, open physician-patient communication rather than a substitute for it.

Future directions for menstrual education

The task for physicians and other sexuality educators with respect to menstrual education is not simple. First, a number of formal and informal partners are involved in the educational process who may provide conflicting information. Second, there are changes in educational processes (e.g., attitudes toward premenstrual symptoms, concepts of the relationship between a girl's experiences at puberty and subsequent identity formation, and information about the relationships between cognitive or affective development, and educational decisions such as the level of abstraction one should use or the timing and sources of information). Third, the success of any program of menstrual education is closely linked to a larger program or experience of sexuality education.

To chart new directions for menstrual education we need to address the components of the educational task and need the support and involvement of physicians in the community. The third component is the most important and incorporates the other two. Menstrual education should not be an isolated educational event. Thus a framework for sexuality education on the basis of lifelong developmental principles is needed. An understanding of young women's physical, emotional, and social development should provide the basis for identification of the needs for a comprehensive sexuality program and the placement of menstrual education within that developmental process. This same understanding will allow physicians and formal educators to recognize the different roles and impact of the various information sources about menstruation. The power of peers, parents, commercial companies, books, and other media as educational agents cannot be ignored. Formal educators in school or community contexts need to be clearer about devising methods to work cooperatively with these other informal educators. The changing knowledge base with respect to sexual functioning demands that educators be diligent in their personal updating. An informed stance allows all of us to evaluate education materials and to challenge current day mythology about sexual functioning.

The general and specialist reproductive physician must accept responsibility in the educational process. Numerous opportunities exist in the medical care setting to establish the rapport needed to answer sensitive questions and concerns that adolescents have about sexuality. Certain attitudes are necessary for the physician when caring for adolescents, particularly willingness to listen and being available to the adolescent when needed. In some cases this may mean adjusting patient practices so that some after-school appointments are reserved for adolescent patients and making efforts to make them feel comfortable when making an appointment or being received by the office personnel. Assumption of care of an adolescent implies that the adolescent, rather than the parent, is recognized as the patient and is treated with the same respect and courtesy as other patients. Adolescents desire a relationship with their physicians on the basis of honesty, respect, expediency, simplicity of education offered, involvement in the therapeutic modality, and encouragement of responsibility for oneself.[22] It is important early in the development of the physician-patient relationship to emphasize the confidentiality of the communication that will occur so that trust may develop. In this case both adolescents and their parents need to understand this principle. Adolescents must feel secure that they are speaking in confidence and may also expect to receive information within a health rather than moral paradigm. Physicians are viewed as respected authorities. On this basis as well as on the basis of a physical examination, the physician can reassure the adolescent of the normality of pubertal developments.

Physicians who desire involvement in the sexuality education of their adolescent patients need to begin to develop effective relationships with them before puberty. Such relationships are characterized by open

communication of feelings and physical concerns. Physicians need to be able to identify the crucial issues of development for these young patients and to initiate the discussion by posing questions and expecting to answer them. Adolescent patients often need "permission" to ask questions about sexuality. Physicians can establish an askable atmosphere by initiating this process. "How are you feeling about growing 6 inches last year?" "How are you feeling about not getting your period at the same age as your best friend? Some girls worry about this but I want you to know that every woman has her own timetable. Don't be afraid to give me or my nurse a call if you have questions about menstruation or sexuality." Information provided to young women should not only be factually accurate but also applied to the young woman's personal concerns. We should recognize that factual information is not all that young women need to know—reproduction is a systemic process and we must address the psychologic impact of the changes as well as the physical. This provides a greater sense of being prepared for puberty.[23]

A well-chosen resource library on puberty, sexually transmitted diseases, and sexual decision making may become a popular extra service for teens and their parents. Booklets should be available in the office but must be previewed before being placed for patients. A reading list could provide an alternative if books or pamphlets cannot be made available. Other methods to provide information and establish an approachable environment are to offer some of these books on a lending basis and schedule a repeat visit for the teen to ask questions or hold special group sessions for teens with the physician and the office nurse. The physician and the office nurse can operate well as an education team within the office structure. Above all physicians must be aware of normal reproductive physiology and be prepared to help young women to develop positive attitudes and an accurate knowledge base of their own reproductive function. Menstrual education needs to move away from the focus on hygienic management to that of healthy sexuality and acceptance of self.

Any sexuality educator has a sensitive task. Calderwood[24] suggests that to prepare for the task effectively there are four essential steps: (1) self-evaluation of one's own attitudes, beliefs, and knowledge of sexuality; (2) unlearning of the debris of myths and misunderstandings that may have been part of the educator's experience; (3) relearning, and finally (4) practice. It is not unusual for physicians to feel uncomfortable handling this task at first. Practice and participation in experiential workshops that address sexuality education or communication can assist the physicians in gaining the confidence that makes the sexuality education process an integral part of adolescent health care. Such a shift to a comprehensive view of menstrual and sex education offers a much greater potential for girls to validate their experience and to integrate this into their sense of self.

Inhibition of pulmonary surfactant function by meconium

David Moses, MD,[a] Bruce A. Holm, PhD,[a, b, c] Patricia Spitale, MD,[b] Mingyao Liu, MD,[a] and Goran Enhorning, MD[a]

Buffalo, New York

The pathophysiology of meconium aspiration is marked by lung hyperinflation because of airway obstruction, which is often followed by an acute pneumonitis with classic lung injury characteristics. Surfactant dysfunction may contribute to this latter pulmonary pathophysiology. We sought to determine to what extent meconium itself might contribute to a functional surfactant deficiency. Specimens of newborn infants' first meconium were collected and pooled. Serial dilutions of the meconium were then added to various concentrations of calf lung surfactant extract, a mixture with the surface properties of natural surfactant that is used clinically to treat neonatal respiratory distress syndrome, and the dynamic surface activity of these mixtures was studied with a pulsating bubble surfactometer. At surfactant concentrations of ≤1.5 mg/ml, even 6500-fold dilutions of meconium-inhibited surface tension lowering ability (10 ± 2 mN/m vs 1 ± 0.1 mN/m for controls, $p < 0.05$). Moreover, this inhibitory activity resided in both the chloroform-soluble and the aqueous phases of meconium and appeared to be additive in nature. However, at sufficiently high concentrations of surfactant, even large amounts of meconium were unable to affect surface tension lowering properties. Thus meconium inhibits surfactant function in a manner that is dependent on the surfactant concentration, suggesting the possible utility of exogenous surfactant therapy in some cases of meconium aspiration. (Am J Obstet Gynecol 1991;164:477-81.)

Key words: Surfactant inhibition, meconium

Meconium is a mixture of bile salts, cell debris, mucopolysaccharides, cholesterol, and enzymes from the fetal intestinal mucosa and biliary tract.[1] Meconium staining of amniotic fluid occurs in 10% to 18% of all deliveries, and 55% of these infants have meconium in the trachea.[2, 3] Meconium aspiration, occurring in 1% to 3% of all term and postterm births, has been associated with severe neonatal respiratory distress characterized by hypoxemia, intrapulmonary shunting, and decreased lung compliance.[2]

Although some of the pathophysiology of meconium aspiration syndrome is clearly related to mechanical obstructions in the airways, previous studies have shown that meconium-induced pulmonary dysfunction may also be related to chemical effects on the lung.[4] These findings have generated comparisons of this component of meconium aspiration syndrome to other forms of disturbed lung function, such as the adult respiratory distress syndrome (RDS).[5]

Adult RDS may lead to acute respiratory failure in both adults and children after a variety of pulmonary or systemic insults, including sepsis, shock, liquid aspiration, pneumonia, oxidant injury, trauma, and many others.[5] Mortality rates for adult RDS have been reported to be as high as 50% to 70%.[5] Recent evidence from this laboratory and others indicates that pulmonary surfactant dysfunction may play a significant role in the development and pathophysiology of adult RDS.[6] The observed surfactant abnormalities in adult RDS appear to be related to the inhibition of surfactant biophysical activity by plasma proteins and other agents that enter the alveolar space during lung injury.[7-11] Moreover, this biophysical inactivation can be avoided by sufficiently increasing the surfactant concentration, suggesting the potential efficacy of exogenous surfactant therapy in adult RDS-type lung injuries.[6-11]

The studies presented here were designed to determine the effects of meconium and its components on

the biophysical activity of pulmonary surfactant. The experiments examined dilutions of meconium or meconium components that were not capable of forming obstructive masses, and their ability to cause surfactant dysfunction, as measured on an oscillating bubble surfactometer.

Material and methods

Preparation of lung surfactant. Natural lung surfactant was obtained by bronchoalveolar lavage of lungs from freshly killed calves as previously described.[12] Briefly, lungs were lavaged three times with 1 L of 0.15 mol/L sodium chloride infused and withdrawn intermittently with a vacuum line. The lavage fluid was centrifuged at 300 *g* for 6 minutes to remove cells and debris, and the supernatant was then spun at 12,500 *g* to pellet phospholipids and associated proteins. This material, subsequently resuspended in 0.15 mol/L sodium chloride, is referred to as natural lung surfactant and is 85% phospholipid and 10% protein.[12]

Preparation of calf lung surfactant extract. Calf lung surfactant extract was prepared from natural lung surfactant by extraction with chloroform and methanol as previously described.[8, 13] The calf lung surfactant extract mixture was >95% phospholipid with a class distribution identical to that of lung surfactant. However, the calf lung surfactant extract protein content was reduced to approximately 2%, representing the low molecular weight, hydrophobic surfactant apoproteins that are required for biophysical activity.[12] For biophysical studies calf lung surfactant extract was dried from chloroform under nitrogen and dispersed in 0.15 mol/L sodium chloride by mechanical mixing. This surfactant preparation has been used extensively in the clinical treatment of neonatal RDS.[13, 14]

Meconium preparation. Meconium samples were collected from 11 healthy infants in the nursery. The meconium was then pooled and blended in a minimal amount of normal saline solution to attain a stock meconium preparation at 130 mg dry weight per milliliter. Aliquots of the meconium pool were stored frozen at −20° C until use. Working meconium solutions were diluted appropriately with normal saline solution.

Meconium extractions. For some experiments meconium was extracted with chloroform and methanol by the method of Bligh and Dyer[15] to separate the water-soluble and chloroform-soluble elements of meconium. Each phase was taken to dryness by nitrogen and heat evaporation and subsequently resuspended at the appropriate concentration in 0.15 mol/L sodium chloride. Aliquots of these materials were stored frozen until use.

Phospholipid analyses. Phospholipid phosphorus analyses were determined by the method of Chen et al.[16] Composition analyses used thin-layer chromatographic techniques with the solvent system of Touchstone et al.[17]

Protein analyses. Protein determinations were done by a sodium dodecyl sulfate modification of the method of Lowry et al.,[18] which allows protein measurements in the presence of high concentrations of lipid.

Surface tension measurement. Adsorption and dynamic surface tension measurements were conducted at 37° C and 100% humidity on a pulsating bubble surfactometer (Electronetics, Amherst, N.Y.) as designed by Enhorning.[19] An air bubble was formed in 25 μl of sample and then pulsated, which compressed the surface area of the bubble by 50%, at a rate of 20 cycles per minute. The pressure difference across the

bubble surface was recorded continuously, and the surface tension values were calculated from the law of Young and Laplace as it applies to spherical surfaces:

$$P = 2\gamma/R$$

where P is the pressure difference across the bubble surface, γ is the surface tension, and R is the bubble radius.

Statistical analyses. Statistical analyses were performed with the Minitab computer software package (Minitab, Inc., State College, Pa.). Analysis of variance was performed on the various mixtures at each surfactant concentration. The unpaired Student *t* test was then performed and compared with control values for those mixtures determined significant by analysis of variance. Statistical significance was assigned for *p* values ≤ 0.05.

Results

Figs. 1 to 3 show the effects of meconium on the dynamic surface activity of pulmonary surfactant as measured on an oscillating bubble surfactometer. The graphs depict the surface tensions at minimal bubble size for various surfactant-meconium mixtures after bubble expansion and 5 minutes of pulsation.

The results in Fig. 1 indicate that at a surfactant concentration of 1.5 mg/ml, as little as 20 μg/ml meconium is capable of causing a significant increase in the minimum surface tension. This meconium concentration, which represents a 6500-fold dilution of the newborn meconium pool, prevented the surfactant mixture from reaching a surface tension below 11 mN/m, a value that is considered to be incompatible with normal physiologic function. Maximal inhibition of surfactant function occurred with 65 μg/ml meconium.

The data in Fig. 2 indicate that pulmonary surfactant at a concentration of 3 mg/ml is also inhibited by meconium, although higher meconium concentrations are required to generate the same degree of inhibition. At this higher surfactant concentration, inhibition of surface activity is first seen at 130 μg/ml meconium, representing a 1000-fold dilution of the natural meconium pool. However, maximum inhibition of surfactant function required 1300 μg/ml meconium. Although this still represents a 100-fold dilution of the original meconium material, the amount of meconium required to inhibit 3 mg/ml surfactant was much higher than one would predict on the basis of a simple stoichiometric interaction between surfactant and meconium.

More important, the results in Fig. 3 indicate that at a surfactant concentration of 6 mg/ml, even the addition of 25 mg/ml meconium, which is only a five-fold dilution of the original pool, was unable to cause significant inhibition of surfactant function. These results indicate that surfactant inhibition by meconium can be overcome at sufficiently high surfactant concentrations.

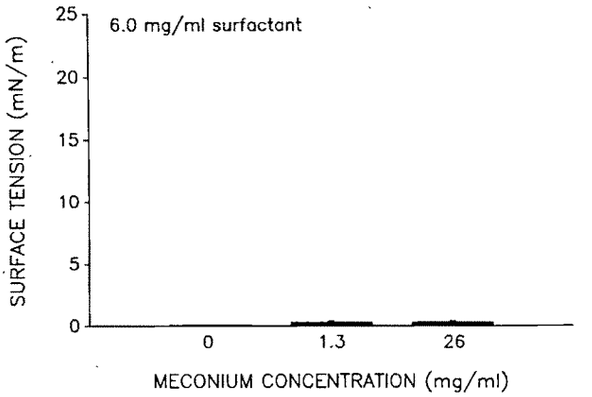

Fig. 3. Effects of meconium on 6.0 mg/ml surfactant. Results represent mean surface tensions at minimum bubble size after 5 minutes of cycling. See text for details.

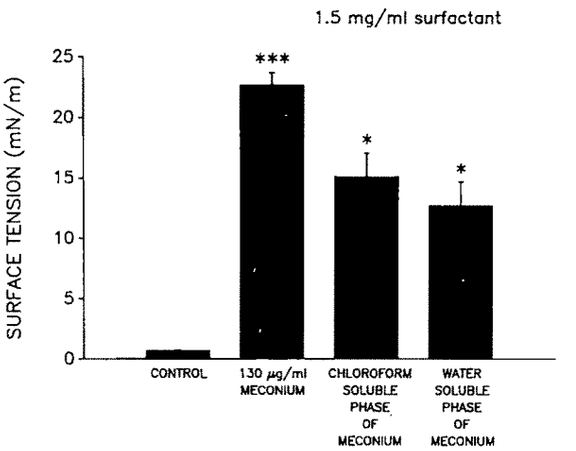

Fig. 4. Effects of meconium components on 1.5 mg/ml surfactant. Total of 130 μg/ml meconium or the associated chloroform-soluble and water-soluble phases were added to 1.5 mg/ml surfactant. See text for details. *Asterisk*, $p < 0.05$; *double asterisk*, $p < 0.005$; *triple asterisk*, $p < 0.0005$.

In an effort to determine the meconium components that are responsible for the surfactant inhibition, further studies were done in which various concentrations of meconium were separated into water-soluble and chloroform-soluble fractions by chloroform-methanol extraction. These components were then added to surfactant suspensions to determine effects on dynamic surface activity as shown in Fig. 4. The data indicate that significant surfactant inhibitory activity resides in both water-soluble and chloroform-soluble phases of meconium, and that the effects after 5 minutes of dynamic cycling appear to be roughly additive.

Comment

The pathophysiology of meconium aspiration syndrome is highly complex and is characterized by hypoxemia, intrapulmonary and extrapulmonary shunting, airway obstruction, and decreased lung compliance.[2,3] Therapy for meconium aspiration has included application of positive-end expiratory pressure, vasodilating agents, and extracorporeal membrane oxygenation.[3,20] The clinical course after meconium aspiration may be as variable as the suggested therapies.

Although many studies concentrate on the airway obstruction and "ball-valve" effects observed in meconium aspiration syndrome, several recent studies have focused on the chemical pneumonitis caused by meconium, suggesting that even small amounts of meconium may be able to produce lung mechanical abnormalities in the absence of mechanical obstructions.[4] The results presented here clearly show that meconium causes significant inhibition of the surface tension lowering properties of pulmonary surfactant. Moreover, these in vitro studies indicate that at lower surfactant concentrations, extremely dilute solutions of meconium are capable of causing a dramatic increase in the minimum surface tension to levels that are incompatible with normal physiologic function. However, at sufficiently high concentrations of pulmonary surfactant, even relatively concentrated meconium preparations were unable to significantly affect the ability of surfactant to lower surface tension under dynamic compression.

These findings are in agreement with previous studies[7-11] that showed that pulmonary surfactant activity can be inhibited by various agents, such as plasma proteins that enter the alveolar space during lung injury. These previous studies also showed that the inhibition was dependent on the surfactant concentration, such that above a threshold surfactant level even exceedingly large amounts of inhibitory proteins were without effect.[9] However, it is clear from the results presented here that the meconium concentrations needed to achieve an inhibitory effect were much lower than those required for plasma proteins and blood cell components.[7,8] Similarly, the necessary surfactant threshold concentration above which inhibition was no longer observed was much higher for meconium and its components than it was for plasma proteins. Thus it appears that meconium may be even more inhibitory of surfactant function than other agents found in the alveoli during different forms of lung injury.

This finding may be due in part to the complex composition of meconium. All individual components of meconium have not been completely defined, but it is known that meconium contains both chloroform-soluble (hydrophobic) components, such as cholesterol, free fatty acids, and glycolipids, and water-soluble (hydrophilic) components, such as mucopolysaccharides and proteolytic enzymes.[1] Our data indicate that both the water-soluble and chloroform-soluble components of meconium are capable of causing significant inhibition of surfactant activity. However, the exact determination of which constituents of meconium are responsible for the surfactant inhibition requires further study.

Similarly, further studies are needed to determine the mechanism or mechanisms by which meconium and its components inhibit surfactant function. On the basis of previous studies by Holm et al.[9] examining the mechanisms for plasma protein-induced inhibition of pulmonary surfactant activity, one might speculate that meconium may inhibit surfactant function by competing with surfactant molecules for space at the air-liquid interface during adsorption or intercalating into the surfactant film during dynamic compression.

The fact that meconium-induced inhibition of surfactant function is dependent on the surfactant concentration has at least two points of practical interest. First, it suggests that localized areas of the lung with a partial surfactant deficiency may be more susceptible to the detrimental effects of small amounts of meconium. Second, the results indicate that meconium-induced pathophysiology related to surfactant inhibition phenomena may benefit from exogenous surfactant replacement therapy. Indeed, previous work by this laboratory[6] showed that the use of surfactant therapy to treat lung injuries with components of surfactant inhibition by proteins resulted in significant amelioration of the associated pathophysiology.

In summary, the studies presented here show that very dilute preparations of meconium are capable of causing significant inhibition of the surface tension lowering properties of pulmonary surfactant, and do so in a manner that is dependent on the surfactant concentration. These results suggest that amnioinfusion with saline solution to reduce the incidence of cord compression and meticulous upper airway suctioning of infants with meconium-stained fluid may be very important. The results also allow us to speculate that exogenous surfactant therapy may prove useful for the treatment of some aspects of meconium aspiration syndrome. Clearly, further studies on the role of surfactant system alterations in meconium aspiration are warranted.

The technical assistance of Lynn Hlavaty and June Sokolowski is greatly appreciated. We also thank Dr. Jean Watawski-Wende for advice on statistical analyses.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The effects of iodoprophylaxis on thyroid size during pregnancy

Rossella Romano, MD,[a,*] Emmanuele A. Jannini, MD,[b,*] Mario Pepe, MD,[b] Alessandro Grimaldi, MD,[b] Michele Olivieri, MD,[b] Patrizia Spennati, MD,[b] Francesco Cappa, MD,[c] and Massimino D'Armiento, MD[b]

L'Aquila, Italy

Thyroid gland size was ultrasonographically determined in 35 pregnant women who live in an area with moderate iodine deficiency. Iodide salt was administered to group A ($n = 17$), whereas group B ($n = 18$) was used as a control. Each group was tested for thyroid-stimulating hormone serum levels, iodine excretion, and thyroid volume. In both groups thyroid-stimulating hormone levels were similar and did not change throughout pregnancy. The iodine excretion at the third trimester in the treated group was significantly ($p < 0.01$) higher than that of group B (100.0 ± 39.0 versus 50.0 ± 37.0 μg iodine per 24 hours, respectively). Initially, thyroid volume did not differ between the two groups. At the end of pregnancy, no difference was found in thyroid size in group A, whereas in the untreated women it increased significantly ($p < 0.0001$) with a mean increase of 1.6 ± 0.6 ml (16.2% ± 6.0%). These results show that the increased thyroid size in the control group was mainly a result of relative iodine deficiency and that iodoprophylaxis should be warranted even in areas with moderate iodine deficiency to prevent the increase in thyroid size and, probably, to avoid the risk of maternal and fetal hypothyroidism. (Am J Obstet Gynecol 1991;164:482-5.)

Key words: Iodine deficiency, iodoprophylaxis, goiter, ultrasonography

The relationship between pregnancy and the thyroid gland has long been recognized and remains a matter of controversy.[1-3] The enlargement of the thyroid gland was once thought to be a characteristic feature of pregnancy and in antiquity a neck measurement was used as a pregnancy test.[4] The goitrogenic effect of pregnancy is partially justified by the effect of estrogen on the production of thyroxine-binding globulin, by the thyroid-stimulating hormone (TSH) activity of human chorionic gonadotropin, and by the effect of thyroid-stimulating immunoglobulins.[5-7] However, it is suggested that the main causative factor is the relative iodine deficiency that occurs during pregnancy as a result of the increase in renal iodine clearance.[8] In fact, epidemiologic studies that report that goiter commonly occurs in pregnancy often derive from investigations conducted in regions where iodine deficiency is common.[9, 10]

The aims of this study are to investigate the thyroid size during pregnancy by use of an accurate ultrasonographic technique and to show the role of iodoprophylaxis in the prevention of an increase in thyroid volume in a group of pregnant women who live in an area with moderate iodine deficiency.

Subjects and methods

Subjects. There was a random selection of pregnant women for the study group from the Obstetrics and Gynecology Department of the University of L'Aquila, L'Aquila, Italy. Only pregnant women who had a normal pregnancy and no personal history of thyroid diseases or other disease abnormalities at the ultrasonographic examination were included. None of the women was pregnant during the previous year and none of the subjects was taking any drugs that could have affected the thyroid hormone metabolism. Pregnant women who had a mean age of 27.1 ± 3.8 years and a mean body weight of 61.6 ± 4.9 kg at the first examination during the first trimester were randomly allotted to group A ($n = 17$). Pregnant women in group B ($n = 18$) had a mean age of 27.1 ± 2.9 years and a mean body weight of 60.9 ± 4.0 kg. All the subjects were born in and live in L'Aquila. The regular smokers (5 to 20 cigarettes per day) were randomly allotted to the two groups. Immediately after the first examination, iodide salt containing 20 mg iodide per kilogram, equivalent to a daily intake of about 120 to 180 μg iodine, was prescribed to all the women in group A.

Each trimester all the pregnant women in both

Table I. Age, body weight, thyroid volume, and iodine excretion at the first evaluation in both groups (mean ± SD)

	No.	Age (yr)		Body weight (kg)	Thyroid volume (ml)	Iodine excretion (μg/24 hour)
		Mean	Range			
Group A	17	27.1	21–35	61.6 ± 4.9	9.8 ± 1.9	37.0 ± 36.0
Group B	18	27.1	23–33	60.9 ± 4.0	10.1 ± 2.3	30.5 ± 42.0

Table II. Iodine excretion (μg/24 hours) in both groups at each trimester (mean ± SD)

	Trimester		
	1	2	3
Group A	37.0 ± 36.0	154.0 ± 59.0*	100.0 ± 39.0†
Group B	30.5 ± 42.0	55.0 ± 35.0	50.0 ± 37.0

*$p < 0.0001$.
†$p < 0.01$ vs first trimester.

groups were subjected to three ultrasonographic evaluations of thyroid volume and to measurement of body weight.

During each examination 24-hour urine samples were taken to determine the iodine urinary excretion by the Riley and Gochman method[11] with a Technicon autoanalyzer. Serum samples were stored at −20° C to test TSH values by ultrasensitive assay (RIAgnost, Behring, Italy). Each patient's samples were analyzed in duplicate in a single radioimmunoassay run. The range of normal values is 0.25 to 4.1 μU/ml and the intraassay coefficient of variation was 3.0%.

Methods. Thyroid volume was measured in all the subjects by ultrasonography with a real-time ultrasound sector scanner (SIM 4000, Esaote Biomedica, Florence, Italy) with a 7.5 MHz transducer. The same investigator was used to obtain ultrasonographic measurements (R.R.) with the subjects in the supine position with hyperextension of the neck. Subsequent measurements were taken not knowing the initial dimensions of the thyroid and to which group the women belonged. The volume of each lobe was determined by use of the formula for the volume of an ovoid: $\pi/6$ (D × W × L),[12] where D is the anterior-posterior dimension of each lobe that was obtained from film images of transverse and sagittal ultrasonographic scans, W is the lateral dimension that was obtained from the film images of the transverse scan, and L is the longitudinal dimension calculated from the film images of the sagittal scan. The sum of the two lobe volumes equals the total thyroid volume. The degree to which repeated computations were reproducible (i.e., the precision of the ultrasonographic method) was estimated by determination of the thyroid volumes in 20 nonpregnant healthy women on day 2 of their menstrual cycles.[13] On the basis of this estimation, the coefficient of variation was 4.8% ± 0.3%.

Informed consent was obtained from each subject.

Values were expressed as mean ± SD. Comparisons were made by use of the Student t test and the linear correlation coefficient between two variables. Significance was defined as $p < 0.05$. Pearson's linear correlation coefficient was used to analyze the association between two variables.

Results

The variables that could influence goiter frequency during pregnancy (i.e., parity, age, body weight, and smoking habits) were similar for both groups studied. At the first evaluation, no significant differences were found with regard to age, body weight, thyroid volume, and urinary iodine excretion (Table I). Similarly, the variation of weight was similar during pregnancy (15.0 ± 4.0 vs 14.3 ± 2.2 kg). In addition, no statistical correlation was found between the percentage of variation of thyroid volume and body weight or age in both groups ($p = 0.78$, $r = -7994$, and $p = 0.87$, $r = 0.046$, respectively).

During pregnancy, TSH levels of all the patients were within the normal range. For each trimester the TSH levels did not statistically differ between women of the same group and between the two study groups.

A significant increase in urinary iodine excretion was found at the second and third examination ($p < 0.0001$ and $p < 0.01$, respectively, Table II) only in group A, treated with iodide salt.

Thyroid volume did not change significantly throughout pregnancy in the group treated with iodide salt, whereas in the control group it increased significantly ($p < 0.0001$), with a mean increase of 1.6 ± 0.6

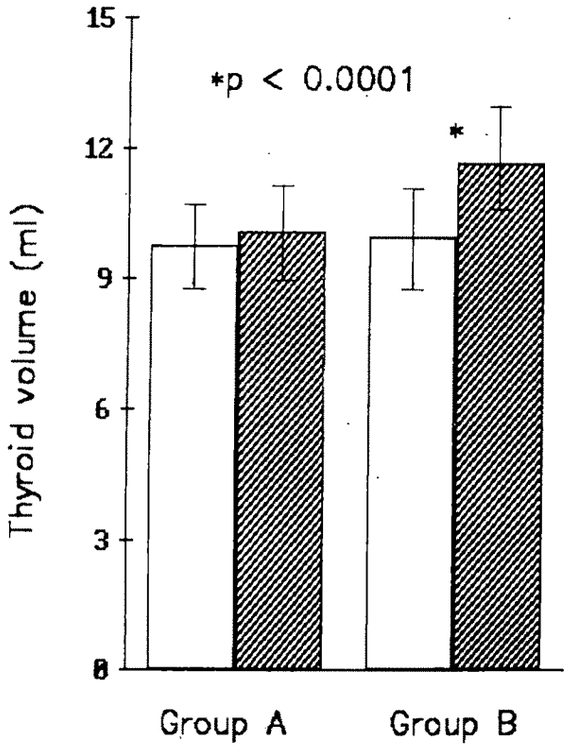

Fig. 1. Variation in thyroid volume (mean ± SD) in 17 women treated with iodide salt (group A) and in 18 untreated women (group B) between the first *(open bars)* and third *(hatched bars)* trimester. (*$p < 0.0001$ vs group A.)

ml (16.25% ± 6.29%) between the first and third trimester (Fig. 1).

Comment

The enlargement of the thyroid gland was once thought to be a characteristic feature of pregnancy.[14, 15] This belief can be questioned from recent epidemiologic observations that failed to show this correlation to geographic areas where iodine intake is adequate.[3] The results of this clinical study showed the need of an adequate dietary iodine intake to prevent the development of a gestational goiter. In addition, we directly showed that iodine deficiency is the main causative cofactor of thyroid enlargement during pregnancy.

In the Abruzzo region the prevalence of a goiter (groups 1B, 2, and 3 of the World Health Organization) in the 8- to 15-year-old population is 41%, mean urinary iodine excretion is 45 ± 12 μg/24 hours, and 98% of the drinking water sources have an iodine concentration <1.3 μg/L.[16] Of all the pregnant women who live in this area, which has a moderate iodine deficiency, only those who use iodide salt and show values of urinary iodine excretion ≥100 μg/24 hours at the third trimester did not have a significant increase in thyroid size. On the contrary, in the untreated group that had lower values of urinary iodine excretion, a significant increase in the mean thyroid volume was observed at the end of the study period. Because urinary iodine excretion accurately reflects dietary iodine intake, one can therefore infer that to prevent the enlargement of the thyroid gland during pregnancy, a minimum intake of 100 μg/day of iodine is required. The iodoprophylaxis with iodide salt containing 20 mg iodide per kilogram ensures an adequate daily iodine intake for the population that lives in this area. However, the recommended reduction in salt intake to prevent gestational hypertension may cause an insufficient iodine intake. In this case, salt with iodide concentration >20 mg/kg should be available.

Contrary to what has been reported by Hegedus,[17] but in agreement with others,[12] our results show that the increase in thyroid volume is unrelated to age and body weight variations. In addition, in agreement with a recent report,[18] TSH serum levels were normal in all the women and did not change during pregnancy. This also applies to the untreated women who showed a significant increase in thyroid volume. This may be explained by the experimental demonstration that alterations in thyroid blood flow are reciprocal to iodine intake levels and appear to be independent of the circulating THS levels. Furthermore, it has been shown that iodine can inhibit thyroid cell growth by a TSH-independent mechanism.[19] Therefore our results confirm that the increased renal iodine clearance is the major pathogenetic mechanism of thyroid gland enlargement during pregnancy.[8]

The urinary iodine excretion of the population studied during the first trimester (Table II) is low when compared with the values recommended by the World Health Organization (150 to 200 μg/24 hours). Because thyroid function abnormalities are frequent under the critical value of 30 μg/24 hours, our population is at risk of development of a syndrome now termed *iodine deficiency disorder*.[20] As far as the mother is concerned, it can cause miscarriages and stillbirths, whereas in the offspring it can cause congenital abnormalities, goiter, hypothyroidism, and impaired brain function.

In summary, in normal iodine intake conditions during pregnancy there is no change in the thyroid volume. This suggests that any enlarged thyroid, even in pregnancy, is diseased. To prevent iodine deficiency disorder, which is the major preventable cause of mental defects in human beings,[20] a supplementation of at least 100 μg/day of iodine during pregnancy should be guaranteed even in moderate iodine deficiency areas.

We thank Paolo Nanni, MD, from the Institute of Endocrinology, University of Pisa, Italy, for the measurements of the urinary iodine excretion, and Paola Minelli and Daniela Di Gregorio for their assistance.

Investigation of placental circulations by color Doppler ultrasonography

Eric Jauniaux, MD,[a, c] Davor Jurkovic, MD,[b] Stuart Campbell, MD,[a] Asim Kurjak, MD,[b] and Jean Hustin, MD, PhD[c]

London, England, Zagreb, Yugoslavia, and Loverval, Belgium

The placental circulations of 25 normal and five complicated pregnancies were studied by color Doppler ultrasonography. Flow velocity waveforms were obtained in all 30 pregnancies and could discriminate between fetal and maternal intraplacental blood flow. We believe that color Doppler ultrasonography will improve our understanding of the pathophysiology of various pregnancy disorders that alter the placental circulations and that color ultrasonography is useful for the prenatal differential diagnosis of intrauterine masses. (AM J OBSTET GYNECOL 1991;164:486-8.)

Key words: Placenta, color flow imaging, Doppler ultrasonography, prenatal diagnosis

Before the development of ultrasonographic techniques our knowledge of the anatomy and physiology of the maternal and fetal placental circulations in human beings had to be extrapolated mainly from data of in vitro perfusion experiments.[1] The advent of Doppler ultrasonography provided us with a new noninvasive method for the in vivo study of the placental circulations. Color Doppler ultrasonography made it possible to image and to investigate small vessels within fetal organs.[2]

The aim of this work is to evaluate the possible applications of color Doppler ultrasonograpny for the study of the morphology and the pathophysiology of the placental circulations.

Material and methods

Thirty singleton pregnancies between 18 and 42 weeks' gestation were studied by means of color Doppler imaging (Aloka Color Doppler SSD-680, Aloka Color Company, Tokyo, Japan).

The study group comprised 25 normal pregnancies, two pregnancies complicated by preeclampsia and intrauterine growth retardation, two pregnancies with hypoechoic tumor of the placental margin, and one pregnancy referred for detailed ultrasonographic examination because of a large heterogeneous intrauterine mass.

Conventional real-time imaging was performed in each pregnancy to identify the different placental structures. With the use of color imaging a prospective search was made for umbilical and chorionic vessels, uterine arteries, and uteroplacental and intraplacental vascular network. For each segment, resistance and pulsatility indexes were measured by spectral analysis of flow velocity waveforms obtained by pulsed Doppler ultrasonography. A nonparametric test (Kruskal-Wallis rank test) was used to determine whether differences in resistance increment between these segments were significant.

Results

Table I summarizes the mean values (± SEM) for resistance and pulsatility indexes obtained from the different segments of the placental circulations.

The waveforms obtained from the fetal side showed the same pattern with a significant decrease in flow resistance going proximal from the fetus into the substance of the placenta (Fig. 1, *A* and *B*).

Within the maternal circulation the resistance also decreased significantly toward the placental bed. A distinct blood flow pattern was found in the terminal segment of the uteroplacental circulation (Fig. 1, *D*). This flow pattern was identified at the level of the maternal plate and up to a few millimeters inside the uterus. It showed a lower resistance and turbulences as compared with the main uterine and radial arteries waveforms. A venous flow pattern (Fig. 1, *C*) was identified in placental sonolucent areas located in the center of the cotyledons or under the chorionic plate.

High-resistance and pulsatility indexes were found in all segments of the uteroplacental circulation in the two pregnancies complicated by preeclampsia. Higher indexes were also found in all segments of the fetal circulation and pathologic examination showed multiple placental infarcts in one of these pregnancies.

In one of the two pregnancies complicated by the presence of a "tumor" at the margin of the placenta,

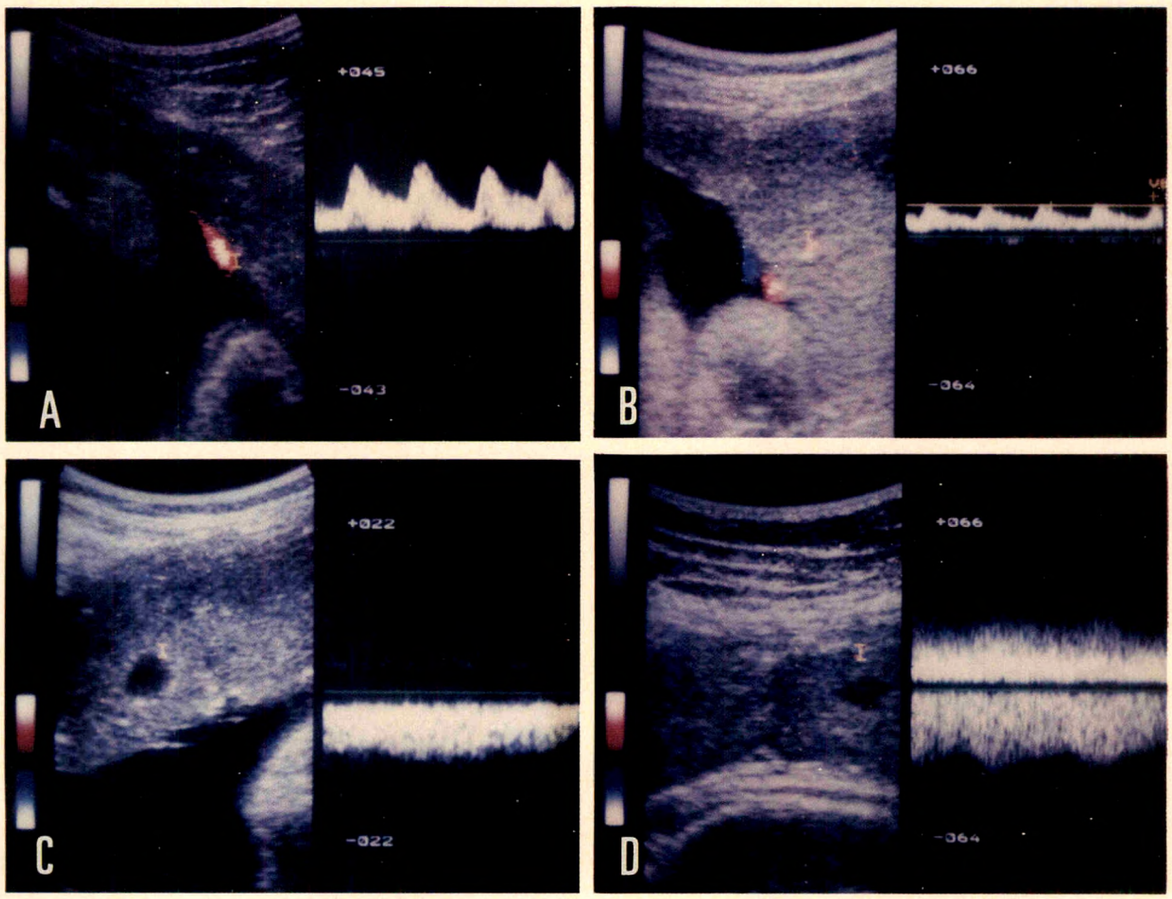

Fig. 1. Color flow mapping and flow velocity waveforms of different segments of fetal and maternal intraplacental circulations. **A**, Chorionic artery at 28 weeks' gestation; **B**, intraplacental arterioles at 32 weeks' gestation; **C**, venous flow pattern in periphery of a sonolucent area at 38 weeks' gestation; **D**, low-resistance turbulent flow at the level of the maternal plate, under a sonolucent area, at 40 weeks' gestation.

the waveforms obtained from the lesion were of maternal origin, suggesting a uterine myoma. In contrast, in the other pregnancy, waveforms with fetal characteristics were identified within the lesion. In the latter pregnany, pathologic examination confirmed the presence of a chorioangioma located at the edge of the placenta.

Color Doppler imaging did not show any blood flow within the abnormal intrauterine mass that was found to be associated with an anatomically normal fetus and a normal placenta. These features suggested molar tissue rather than a degenerating myoma or another uterine tumor where maternal signals would be expected. Pathologic investigations showed a twin pregnancy that combined a classic hydatidiform mole and a normal pregnancy.

Table I. Mean values (± SEM) for resistance and pulsatility indexes obtained from the placental circulations

	Resistance index	*Pulsatility index*
Fetal circulation		
Umbilical artery	0.662 ± 0.027	1.145 ± 0.050
Chorionic artery	0.564 ± 0.017*	0.848 ± 0.035*
Intraplacental arteriole	0.461 ± 0.014*	0.692 ± 0.040†
Maternal circulation		
Uterine artery	0.559 ± 0.014	0.916 ± 0.051
Radial artery	0.404 ± 0.010*	0.546 ± 0.020*
Spiral artery	0.326 ± 0.008*	0.422 ± 0.018*

*$p < 0.001$ significantly different increment from preceeding value (Kruskal-Wallis rank test).

†$p < 0.01$ significantly different increment from preceeding value (Kruskal-Wallis rank test).

Comment

Color Doppler ultrasonography is changing our ability to map the fetal and maternal components of the placental circulation. In this study, small branches of both uterine and umbilical cord arteries were clearly visualized with the color mode (Fig. 1). The two-dimensional display of these vessels allowed accurate placement of the pulsed-Doppler gate for spectral anal-

ysis. Identification of chorionic vessels, intraplacental fetal arterioles, terminal branches of the uteroplacental vessels, and intervillous blood flow could be easily performed in all pregnancies. A significant fall of resistance on both fetal and maternal sides was observed (i.e., from the umbilical artery to chorionic arteries and to intraplacental arterioles and from the uterine artery to the radial and spiral arteries; Table I).

The overall structure of placental vasculature as shown with color imaging and spectral analysis correlated well with the classical anatomic findings.[1] Normal placentas at term contain avillous cavities of various sizes and shapes located mainly in the center of the cotyledons. Perfusion studies in vitro showed that these cavities are a result of the spurt of maternal blood that comes from the spiral artery and pushes away the surrounding villous tissue.[1] Sonolucent spaces identified by real-time imaging contain turbulent flow on color imaging with a venous pattern on spectral analysis (Fig. 1, *C*). When the Doppler gate is moved from these spaces toward the basal plate of the placenta, waveforms with distinct maternal characteristics and assumed to derive from the spiral arteries can be seen (Fig. 1, *D*). Accurate identification of these flows appears promising in understanding the pathophysiology of placental vascular lesions such as thrombosis or infarcts and placental insufficiency.

Knowledge of the expected fetal or maternal waveform characteristics is also important if color Doppler ultrasonography is to have a role in differential diagnosis between placental and other intrauterine abnormalities. For instance, in cases of undetermined placental mass, demonstration of fetal waveforms strongly suggests chorioangioma, whereas maternal waveforms favor the diagnosis of a uterine myoma.

Reduction of cardiovascular disease–related mortality among postmenopausal women who use hormones: Evidence from a national cohort

Pamela H. Wolf, DrPH,[a] Jennifer H. Madans, PhD,[b] Fanchon F. Finucane, MHS,[b] Millicent Higgins, MD,[c] and Joel C. Kleinman, PhD[b]

Bethesda and Hyattsville, Maryland

A national sample of 1944 white menopausal women ≥55 years old from the epidemiologic follow-up of participants in the National Health and Nutrition Examination Survey was reviewed to investigate the role of hormone therapy in altering the risk of death from cardiovascular disease. Women in the study were observed for up to 16 years after the baseline survey in 1971 to 1975. By 1987 631 women had died; 347 of these deaths were due to cardiovascular disease. History of diabetes (relative risk, 2.38; 95% confidence interval 1.73 to 3.26), previous myocardial infarction (relative risk, 2.12; 95% confidence interval 1.56 to 2.86), smoking (relative risk, 2.18; 95% confidence interval, 1.69 to 2.81), and elevated blood pressure (relative risk, 1.49; 95% confidence interval, 1.14 to 1.94) were strong predictors of cardiovascular disease–related death in this cohort. After adjusting for known cardiovascular disease risk factors (smoking, cholesterol, body mass index, blood pressure, previous myocardial infarction, history of diabetes, age) and education, the use of postmenopausal hormones was associated with a reduced risk of death from cardiovascular disease (relative risk, 0.66; 95% confidence interval, 0.48 to 0.90). The same protective effect provided by postmenopausal hormone therapy was seen in women who experienced natural menopause (relative risk, 0.69; 95% confidence interval, 0.45 to 1.06). (AM J OBSTET GYNECOL 1991;164:489-94.)

Key words: Postmenopausal, hormones, cardiovascular, mortality

Whether the administration of estrogen replacement therapy after menopause provides some degree of cardiovascular protection is currently a subject of debate. Cardiovascular disease is a leading cause of death among women. However, the age-specific death rates for cardiovascular disease among women are substantially less than those of men the same age. The fact that the disparity is less pronounced after age 60 has led some investigators to conclude that the protective effect is due to the production of endogenous estrogens and/or other functions of the ovaries. Furthermore, it has been hypothesized that the use of exogenous estrogen after menopause will sustain this advantage at the older ages. Several studies have shown that women who undergo estrogen replacement therapy enjoy a substantial advantage with regard to fewer cardiovascular events,[1-6] whereas other studies show little or no effect of estrogen replacement,[7, 8] and in some cases an increase in cardiovascular disease is demonstrated.[9, 10] The mortality studies[1-6] are based on a small number of deaths, primarily because of short follow-up periods.

A sufficiently large cohort with adequate follow-up is required to conclusively resolve the issue of the putative protective effect of hormone replacement therapy in menopausal women. The National Health and Nutrition Examination Survey (NHANES I) Epidemiologic Follow-up Study provides information on such a cohort. This cohort consists of a nationally representative sample of women from the United States, who, after >15 years of observation, have experienced the largest number of cardiovascular disease–related deaths reported to date in a prospective study. Furthermore, the study was conducted in an era in which the prescribing practice for estrogen replacement consisted almost exclusively of conjugated equine estrogen (Premarin).[11] This cohort is used to investigate the influence of postmenopausal hormone therapy on car-

6/1/25553

diovascular disease mortality and to study whether this effect varies with the type of menopause.

Material and methods

Study population. The NHANES I Epidemiologic Follow-up Study is a longitudinal study that is designed to investigate the relationships among clinical, nutritional, and behavioral factors measured at the NHANES I in 1971 to 1975 and to examine subsequent morbidity and mortality among study participants. The study attempted to trace and reinterview adult subjects (or their proxies), who ranged in age from 25 to 74 at the NHANES I (baseline). Hospital and nursing home records were collected to determine any overnight stays that had occurred since the baseline examination. Death certificates were obtained for the decedents. More detailed discussions of the design, operation, and content of both the NHANES I and the Epidemiologic Follow-up Study are described elsewhere.[12]

The first wave of the follow-up, which was conducted from 1982 to 1984, resulted in information on nearly 93% of the follow-up group. Additional waves were conducted in 1986 (for those at least 55 years old at baseline) and again in 1987. The analysis reported here is restricted to white female subjects in the NHANES I Epidemiologic Follow-up Study who were at least 55 years old and menopausal at the time of the baseline survey. More than 96% of these eligible women were successfully traced at some time during the follow-up. Only women who had complete information on the cardiovascular risk factors under study, including the use of postmenopausal hormones, were considered in this analysis.

Risk factors. For the purpose of this study, menopause is defined as the complete cessation of menstruation as reported at baseline; timing of menopause is based on baseline information concerning whether menses ceased before age 45 (early menopause). Type of menopause was categorized as natural or surgical, on the basis of information obtained in the inverview. Cardiovascular risk profiles at baseline were defined according to the following criteria. Smoking status at baseline was determined either directly from the baseline questionnaire or from the lifetime smoking history taken at the first follow-up interview, or it was imputed in the case of missing information. Women were categorized as smokers if they reported at baseline that they were currently smoking. High cholesterol was defined according to the 1984 National Institutes of Health Consensus Development Conference (>260 mg/dl).[13] Body mass index in metric units is computed as weight [kilograms]/(height[meters])^2 and is categorized into quartiles on the basis of all women who were menopausal at baseline. High blood pressure is defined as systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg.[14] Prevalence of diabetes at baseline and history of myocardial infarction were based on self-reported data. Women were categorized as either ever-users or nonusers of postmenopausal hormones, on the basis of questions asked in the 1982 to 1984 questionnaire. Since this information was obtained by self-report, it is subject to some recall bias. In addition, a proxy respondent provided the information on hormone use for subjects that were deceased or incapacitated at the time of the 1982 to 1984 interview. The complexities associated with use of proxy information are addressed below.

Cardiovascular disease mortality. Vital status was ascertained in the 1982 to 1984, 1986, and 1987 waves of the follow-up. Mortality information was obtained from either a death certificate and/or a proxy respondent. The underlying cause of death was coded by rules of the *International Classification of Diseases*, 9th revision (ICD-9), for the 96.6% of the decedents in this menopausal cohort with an available death certificate. In this study mortality from cardiovascular disease is defined as underlying cause of death coded to ICD-9 390-459. Decedents with no death certificate (3.4%) were omitted from the analysis.

Statistical analysis. Relative risks were estimated with the Cox proportional hazards model and the PHGLM procedure in the SAS software system.[15] This procedure takes into account the variable length of follow-up, which is computed from the time of the baseline survey to the last known date alive and which ranged from 11.4 to 16.3 years among the survivors (average, 14.1 years) and 2 months to 16.3 years among the decedents (average, 8.6 years). First, we computed the estimated relative risks for known cardiovascular risk factors (smoking, elevated cholesterol, high body mass index, elevated blood pressure, history of diabetes, previous myocardial infarction, age at examination), age at menopause, and use of hormones for treatment of menopause. Since estrogen depletion is more abrupt and since the use of hormones is more common after surgical menopause, it was of interest to specifically evaluate the role of hormone replacement after natural menopause, when estrogen replacement is optional and is often determined by the level of discomfort of the patient. Because hormone use may be related to health care access and utilization, which are greater among women of higher socioeconomic status, all models included education as a measure of socioeconomic status.

Two potential sources of bias that might affect these analyses were investigated. Bias might have been introduced by elimination of subjects with missing or unknown hormone use data (12%). To examine this, we reanalyzed the data by imputing hormone use for missing values. Three imputed values were created accord-

ing to the following criteria: (1) women with unknown estrogen status were as likely to use estrogen as were women with know estrogen status; (2) estrogen use was twice as likely to occur among the unknown as the known; (3) estrogen use was one half as likely to occur among the unknown as the known. All three imputations were applied within age-at-examination strata. Bias also might have been introduced by allowing proxy responses to the hormone question. To evaluate this particular bias, relative risk estimates were recomputed for subjects who survived to the 1982 to 1984 interview and who responded to the interview themselves. This precaution eliminated all proxy respondents from the study.

Results

A total of 2461 white female subjects from the NHANES I Epidemiologic Follow-up Study were identified as postmenopausal and at least 55 years old at baseline. Subjects were eliminated from final analysis because of unknown age at menopause ($n = 62$), inability to determine cardiovascular risk status at baseline ($n = 90$), unknown level of education ($n = 10$), loss to follow-up ($n = 71$), and missing information on hormone use at the 1982 to 1984 follow-up ($n = 284$). Table I shows the characteristics of the remaining 1944 women. The mean age of the cohort at baseline (1971 to 1975) was 65.7 years. Nearly 19% of the women were smokers, almost 40% had elevated cholesterol levels, and 67.7% had elevated blood presure. Overall, 62.4% began follow-up with two or more known cardiovascular disease risk factors. By the initial recontact from 1982 to 1984, 367 deaths (18.9%) had occurred. An additional 264 deaths occurred between 1982 to 1984 and 1987. Overall, 347 of the 631 deaths resulted from cardiovascular disease.

The characteristics of the cohort by hormone use and type of menopause are given in Table II. There were 1377 women (70.8%) who experienced natural menopause, 430 women (22.1%) who reported a surgically induced menopause, and 137 women (7.1%) for whom the type of menopause could not be determined. The table is based on the 1807 women for whom information on the type of menopause was available. Hormone use was nearly three times higher in the surgical menopause group, as compared with use in women undergoing natural menopause (38.4% vs 15.5%, respectively). Hormone users in general had lower blood pressure, lower prevalence of diabetes, and lower body mass index at baseline. On the other hand, when compared with nonusers, women using postmenopausal hormones had a higher prevalence of smoking. Cholesterol levels and history of myocardial infarction were the same for both hormone users and nonusers. The risk factor profile of women undergoing natural menopause was virtually the same as that of the surgical menopause group, although the surgical group had a slightly higher percentage of women with a history of previous myocardial infarction (7.9% vs 6.8%). Over half of the women in the sample had two or more cardiovascular risk factors present at baseline, regardless of type of menopause and hormone use history; only 8% were free of the risk factors under study.

†>29.5.

‡Systolic blood pressure >140 mm Hg or diastolic pressure >90 mm Hg.

When multivariate risk estimates for cardiovascular disease mortality were generated for the cohort (Table III), age, history of diabetes, smoking, and elevated blood pressure were strong predictors. Individuals in the third quartile of body mass index (25.5 to 29.4) experienced a reduced risk of cardiovascular disease–related death, as compared with the risk in individuals in the lowest quartile. Elevated cholesterol, early menopause (age <45), and education did not alter cardiovascular disease–related mortality risk for women in this cohort.

Hormone use was associated with a 34% reduction in cardiovascular mortality risk (relative risk, 0.66; 95% confidence interval, 0.48 to 0.90) after adjusting for known cardiovascular risk factors and education. A separate model for natural menopause was generated to investigate whether elective use of hormones provides the same level of protection. The adjusted relative risk for hormone use among women experiencing natural menopause was 0.69 (95% confidence interval, 0.45 to 1.06) (Table IV). This effect was smaller in the surgical menopause group (not shown) for whom the estimate of cardiovascular disease–mortality risk was 0.80 (95% confidence interval, 0.39 to 1.67). The confidence intervals surrounding this estimate are wider, because of

both the small number of women undergoing surgical menopause ($n = 430$) and the few cardiovascular disease deaths ($n = 37$) in this group.

To investigate the effect of proxy responses, the estimates were recomputed for the subgroup of women who survived until the 1982 to 1984 interview. This analysis is based on the 135 cardiovascular disease deaths that occurred between 1982 and 1987. This eliminates proxy responses to the hormone questions. The overall relative risk for cardiovascular disease mortality among hormone users in this group of menopausal women was consistent with a protective effect although to a lesser degree (relative risk 0.80; 95% confidence interval, 0.50 to 1.26), as was the estimate for women experiencing natural menopause (relative risk 0.80; 95% confidence interval, 0.44 to 1.52). The confidence intervals for both estimates are much wider. The relative risk estimates that were generated with the random assignment of the estrogen variable for missing data (not shown) did not differ substantially from those given in Tables III and IV. These results indicate that two potential sources of bias (missing data and proxy responses) do not appear to have affected the findings presented in this investigation.

Comment

The current study demonstrates a reduction in cardiovascular disease–related mortality among women who use postmenopausal hormones. Relative to women who had never taken hormones, the reduction in risk is 34%. This protective effect is not explained by known or suspected cardiovascular risk factors or by the timing of the menopause, and the effect persists despite the prevalence of two or more cardiovascular disease risk factors at baseline in half the hormone users. We have attempted to examine two potential sources of bias (missing hormone use information and the use of proxy responses) by performing additional analyses in which we imputed the hormone use data on the basis of three different assumptions and restricted the analysis to subject reponses only. Although the resultant analyses yielded wider confidence intervals, they also indicated a protective effect.

It is important to recognize that in many observational studies users and nonusers of estrogen differ at baseline with respect to important cardiovascular risk factors such as smoking, body mass index, and blood pressure. We have attempted to adjust for differences in cardiovascular disease risk factors by including them in the statistical model.

It should be noted that the scope of cardiovascular disease mortality in this study is much broader than that in earlier mortality studies and that this study includes death from cerebrovascular disease. Nevertheless, the results are similar in the magnitude of the protective effect of postmenopausal estrogens found in

studies limited to ischemic heart disease deaths. Thus our findings suggest that the protective effect of postmenopausal hormones extends beyond that provided for ischemic heart disease.

Of the cohort studies to date that have examined the relationship between postmenopausal hormone use and cardiovascular disease,[3-6, 8, 9] most have found estrogen to be protective. However, two of the larger prospective studies report contradictory findings. The Nurses Cohort Study[3] showed that estrogen replacement therapy reduced the risk of severe coronary heart disease and that the increase in cardiovascular disease associated with surgical menopause could be prevented by estrogen replacement therapy. However, the Framingham study[9] suggested that women who used postmenopausal estrogen were subject to an increase in the development of cardiovascular disease and indicated that rates of myocardial infarction were increased among estrogen users who smoked, whereas cerebrovascular disease rates were increased among nonsmokers. In subsequent analyses[16] of the Framingham cohort postmenopausal estrogen use was not related to the incidence of serious coronary disease among women aged 50 to 59, but an association among women aged 60 to 69 was noted. Despite the large cohort sizes and ample follow-up periods, both these studies generated few cases of cardiovascular disease, in part because of the age of the women at entry into the study. In contrast, this investigation is a large, heterogeneous, national sample followed up for a maximum of 16 years, which has yielded the largest number of cardiovascular disease–related deaths reported in a prospective study to date.

Although the use of postmenopausal estrogens declined to some degree in the mid-1970s, when it was associated with an increase in endometrial cancer,[17] the use of estrogens has increased in recent years, although they are administered at lower prescribed doses and are often administered with a progestational agent. A recent survey of gynecologists[11] showed that 94% routinely administer estrogens for postmenopausal therapy, which shows an increase from 79% 10 years ago.

Table IV. Relative risk of cardiovascular disease–related mortality for white women using postmenopausal hormones, compared with that for nonusers, for total cohort and for women experiencing natural menopause, by type of response from women aged >55 and menopausal at baseline (NHANES I Epidemiologic Follow-up Study)

*Hormone users as compared with nonusers.

†Adjusted for age, smoking, blood pressure, cholesterol, body mass index, diabetes, previous myocardial infarction, and education, with use of the Cox proportional hazards model.

More than 2 million women are currently using estrogen for noncontraceptive reasons each year.[18]

Hormone therapy is one of the possible interventions that can improve a woman's cardiovascular status. The findings presented here indicate that prevention of 20% to 35% of the cardiovascular deaths experienced by women who do not use estrogen is possible. This benefit must be weighed against the potential risks, such as gallbladder disease, high blood pressure, thromboembolic disease, impaired glucose tolerance, and endometrial cancer, which are associated with estrogen therapy.[19] However, the combined incidence rates of these adverse effects are exceeded by that of heart disease.

Although the baseline and 1982 to 1984 questionnaires do not explicitly acquire information about specific estrogen preparation used, Premarin was used in 95% of the estrogen therapies; that use has remained constant during the last decade. Current prescribing practices indicate a trend toward combined therapy. Whether the addition of a progestational agent will diminish the beneficial effects of estrogen is unknown. New questions added to the most recent interview of this cohort in 1987 addressed issues of dose and the addition of a progestational agent. This analysis used a limited definition of hormone use (ever-use vs never-use). Future analyses will incorporate additional aspects of patterns of use, such as timing and duration, to further specify the nature of the relationship between hormone use and cardiovascular disease mortality. Clinical trials are also needed to investigate new preparations of estrogen and progestational agents for hormone replacement, as well as to determine alternative routes of administration such as patches and implants.

Endosalpingosis as a cause of chronic pelvic pain

Susan A. Davies, MD, and Victoria M. Maclin, MD
Chicago, Illinois

Endosalpingosis, a condition characterized by ectopic oviduct epithelium, is diagnosed histologically by the appearance of benign ciliated and nonciliated columnar cells in an abnormal location. Endosalpingosis is typically without symptoms. Our unusual case report shows symptomatic endosalpingosis first seen with chronic pelvic pain. Various aspects of this disease will also be discussed. (Am J Obstet Gynecol 1991;164:495-6.)

Key words: Endosalpingosis, pelvic pain, ectopic tubal epithelium

Endosalpingosis is a condition characterized by ectopic oviduct epithelium.[1] Typically endosalpingosis is diagnosed histologically by the appearance of benign ciliated and nonciliated columnar cells, along with peg cells, in an abnormal location.[1] Macroscopically this disease is usually not detectable. When visually obvious, endosalpingosis can be seen as multiple, punctate (1 to 2 mm), white to yellow, opaque or translucent, fluid-filled, cystic lesions that grossly impart a granular appearance to the involved peritoneal area as exemplified by the following case report.[2] Rarely, larger cysts may be present.

Case report

A 19-year-old white gravida 0 female was first seen with pelvic pain. Her pain had progressed since menarche from dysmenorrhea to occasional intermenstrual pain to virtually constant pain. She began menarche at age 14 years. Severe menorrhagia and dysmenorrhea resulted in her being placed on oral contraceptives soon after menarche; however, oral contraceptives were discontinued by age 15 years because of depression. Cessation of oral contraceptives resulted in resumption of progressive dysmenorrhea.

Multiple medical opinions were sought for pain relief. In November 1988 she underwent diagnostic laparoscopy. Biopsy specimens of the pelvic peritoneum revealed "a few ciliated polygonal-epithelial lined cysts with a focal underlying endometrial-type stroma consistent with endometriosis foci." Subsequently, she underwent 6 months of Danocrine therapy for suppression of endometriosis. Dosage during the first 5 months was 800 mg per day. However, during the sixth month, because of persistent vaginal bleeding and despite having achieved pain relief, her dose was increased to 1000 mg per day. Discontinuation of therapy was followed by rapid resumption of pelvic pain, leading to a second laparoscopy at another institution in May 1989. Pelvic inspection at that time revealed "miliary dissemination of minute particles and nodules between 0.5 mm and 2 mm in diameter." These biopsy specimens were histologically described as "atypical cysts, rule out ruptured serous cystadenoma of ovary," despite normal appearance of the ovaries at the time of laparoscopy.

The patient was referred to Rush–Presbyterian–St. Luke's Medical Center, Section of Gynecologic Oncology, where slides from the previous biopsy specimens were reviewed and a diagnosis of endosalpingosis was made. She was referred in August 1989 to the Section of Reproductive Endocrinology for hormonal suppression with a gonadotropin-releasing hormone agonist. She reported a progressive decrease in pain during the previous month. A urinary β-human chorionic gonadotropin test was performed (because of persistent amenorrhea during the 4 months since discontinuation of Danocrine therapy) and was positive. Pelvic examination revealed a 7-week-size uterus and vaginal ultrasonography indicated a 7½–week intrauterine pregnancy. In view of her pregnancy and decreasing pelvic pain, no medication was prescribed.

Comment

Endosalpingosis was first described in 1930 by Sampson.[3] His study of 100 cases of tubal stumps after tubal ligations led to the observation that sprouts of fallopian tube epithelium often invade the wall of the stump and may even extend beyond it after healing is complete.[3] Endosalpingosis is typically located in the visceral pelvic peritoneum covering the uterus, fallopian tubes, ovaries, and cul-de-sac. Less frequent locations involve the pelvic parietal peritoneum, omentum, bladder and bowel serosa, periaortic area, and within the skin.[2] Endosalpingosis is commonly associated with previous tubal surgery such as tubal sterilizations and salpingectomies and is also associated with chronic salpingitis.[1] Furthermore, it is usually a process without symp-

6/1/25746

toms, noted incidentally by a pathologist on a histologic specimen. It is of interest that symptomatic endosalpingosis (unlike the condition without symptoms) is associated with psammoma body formation.[2]

The various hypotheses as to the cause of endosalpingosis are: (1) transplantation, tubal mucosa is transplanted to peritoneal surfaces, usually during surgery; (2) direct extension, tubal epithelium extends to the peritoneum as exhibited by adhesion formation; (3) reactive, salpingitis causes tubal epithelium to proliferate with repair being the goal and retrograde spill results; (4) coelomic metaplasia, coelomic peritoneum cells are multipotential and can differentiate into oviduct epithelium; and (5) lymphatic-vascular spread.[2]

It is important to rule out endosalpingosis when endometriosis is being considered because both have been reported in the same person. Endometriosis is histologically characterized by the presence of endometrial glands and stroma. Furthermore, endometriosis often has a hemorrhagic appearance as a result of this tissue's response to hormonal stimuli. Endosalpingosis, as stated previously, is histologically characterized by the appearance of benign ciliated and nonciliated columnar cells in an abnormal location. Endosalpingosis does not exhibit a hemorrhagic response to hormonal stimuli, which further helps in the differentiation of this condition from endometriosis. Also metastasis from ovarian papillary serous tumors must be differentiated from endosalpingosis inasmuch as both may have psammoma bodies and endosalpingosis may form a papillary configuration as a result of irritation, trauma, or manipulation. Histologic features that support the diagnosis of metastasis from an ovarian papillary serous tumor include the presence of an infiltrative pattern, a desmoplastic stromal response, the presence of only one cell type, and the absence of a basement membrane surrounding the glands.[2] The latter morphologic features do not characterize benign endosalpingosis.

In summary, endosalpingosis is a benign disease that is diagnosed histologically by the presence of ectopic oviduct epithelium. Our patient exhibits several unusual aspects of this process. First, the extent of the disease is evident macroscopically with the apparent miliary dissemination. Also, our patient is symptomatic, contrary to the usual presentation without symptoms. Although the cause of this disease remains unknown, it is likely that several of the proposed hypotheses may actually play a role. To date there is no known treatment protocol for endosalpingosis, but hormonal suppression regimens commonly used for endometriosis may be of benefit in this special group of patients as exemplified by our case report.

Transvaginal ultrasonographic definition of the central nervous system in the first and early second trimesters

Ilan E. Timor-Tritsch, MD, Ana Monteagudo, MD, and Wendy B. Warren, MD
New York, New York

A 6.5 MHz transvaginal sector scanner was used to describe the fetal central nervous system anatomy from 6 to 14 weeks. One hundred thirty-three pregnant patients were scanned after the crown-rump measurements were found to be within a range of ≤4 days from menstrual age. The number of possible ultrasonographic sections ("slices"), as well as the number of successful views in the axial, coronal, and sagittal sections, was tabulated. A detailed list of central nervous system structures that are seen at each gestational age is presented. The results showed that a significant number of brain structures could be imaged. The number and the clarity of the structures and the number of successful views in the three scanning planes increased with gestational age. We concluded that transvaginal scanning for central nervous system maldevelopment can be started in the late first and early second trimesters. (Am J Obstet Gynecol 1991;164:497-503.)

Key words: Transvaginal ultrasonography, central nervous system, fetus, first trimester, second trimester

High-frequency transvaginal ultrasonography has been shown to be useful in imaging early pregnancy.[1-4] Previous work has been published which stresses its potential use in the malformation workup of the first and early second trimesters.[5, 6] To facilitate the proper clinical application of transvaginal ultrasonography from 6 to 14 weeks, a study that describes the chronologic appearance of normal central nervous system structures was undertaken.

Patients and methods

Patients. Transvaginal ultrasonography was performed on 133 women with low-risk pregnancies and singleton fetuses. Only one scan for each fetus was used for the purposes of this study.

Dating of the gestation. The gestational age by menstrual history was compared with the gestational age by the crown-rump length.[7] Only those cases with a discrepancy that was ±5 days were included in the study. In 98 of the 133 cases this discrepancy was <3 days. The distribution of the patients by gestation is shown in Table I.

Equipment. A single-element vaginal sector scanner probe, which operated at 6.5 MHz, was used (Elscint, Inc., Haifa, Israel).

Scanning planes attempted. Sagittal, axial, and coronal planes of the fetus were sought. A note was made

of the number of subsequent sections that could possibly be studied for each fetus.

Successful views across each plane. For each gestational age group, we recorded the number of cases in which a structure was adequately evaluated.

Correlation. Correlation of the detected structures with the appropriate structure in embryology textbooks was also attempted for each gestational age.[8-10]

It is beyond the limits of this article to present images of all of the detected structures throughout each week of gestation. Only a small number of selected images are included in this section.

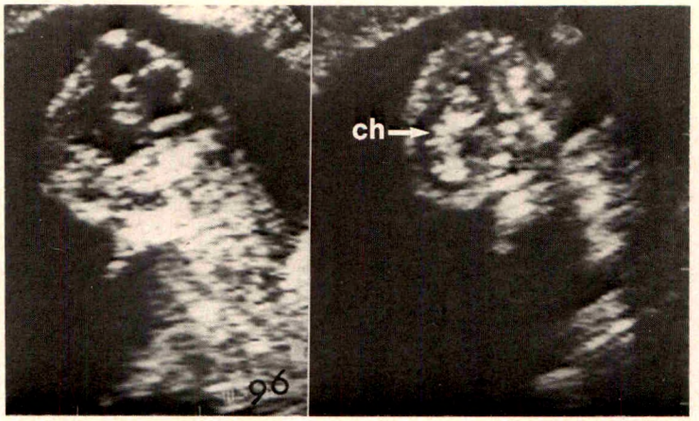

Fig. 2. At 9 weeks 6 days a midsagittal section reveals more detail of the convoluted cavities of the brain *(left side)*. The parasagittal section shows the lateral ventricle hosting the hyperechoic choroid plexus *(ch) (right side)*.

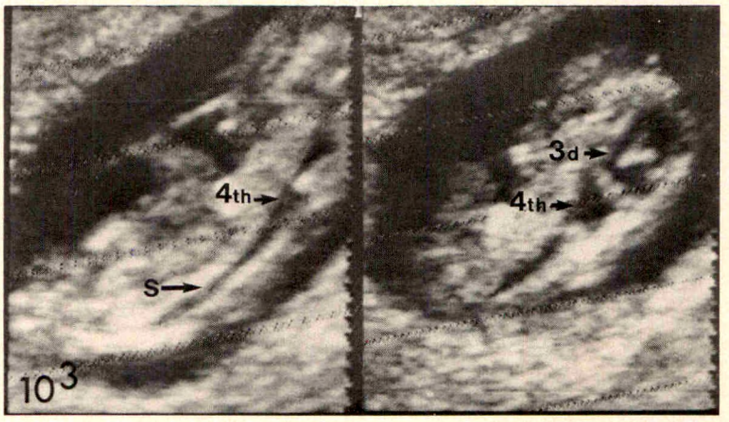

Fig. 3. Two subsequent coronal sections of the fetus at 10 weeks 4 days, which demonstrate the spinal canal *(S)*, fourth ventricle *(4th)*, and third ventricle *(3d)*.

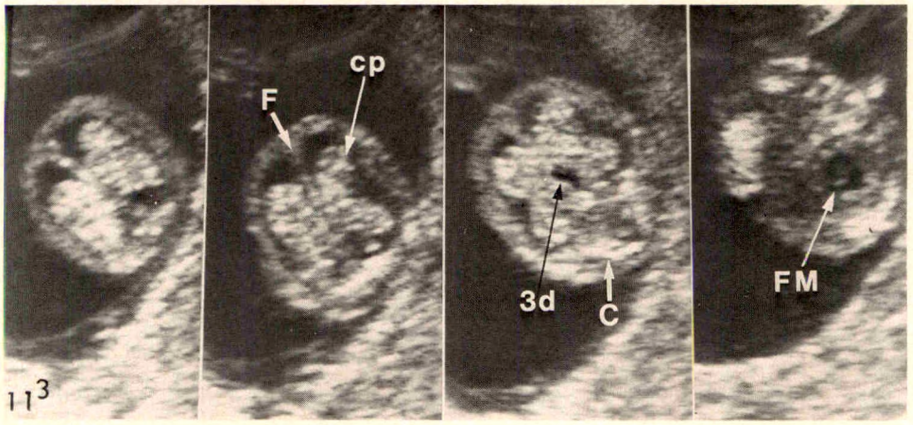

Fig. 4. Four serial axial sections at 11 weeks 3 days, starting at the top *(left)* and ending with the one taken at the base of the skull. Structures seen are the falx *(F)*, choroid plexus *(cp)*, third ventricle *(3d)*, cerebellum *(C)*, and foramen magnum *(FM)*.

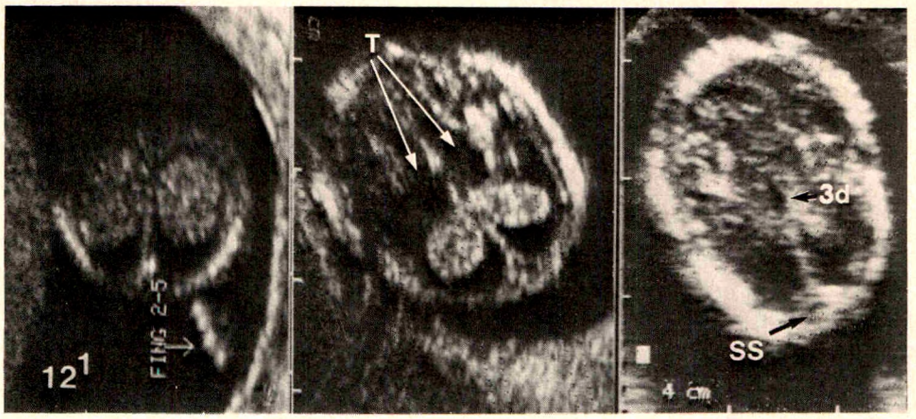

Fig. 5. At 12 weeks 1 day the coronal section (left) shows the falx and choroid plexus. The axial sections (*middle* and *right*) reveal the hyperechoic choroid plexus on top of the thalami *(T)* in the lateral ventricles. Only a thin cortical mantle is still seen. The third ventricle *(3d)* and the frontal part of the sagittal sinus *(SS)* are also seen.

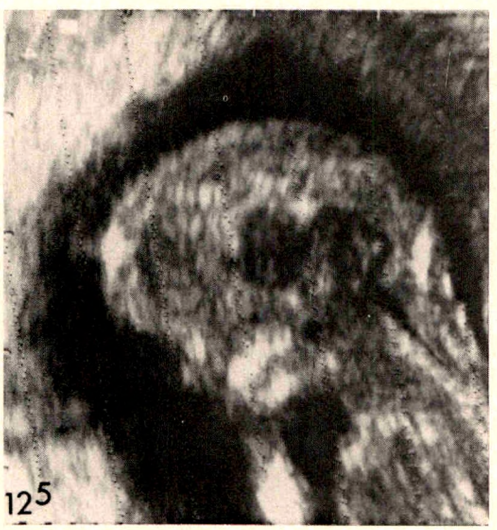

Fig. 6. A midline sagittal section at 12 weeks 5 days shows the sonolucent convolutions of the ventricular system leading into the spinal canal.

Results

The number of sections that were obtained in each plane from 6 to 14 weeks is shown in Table II. During the time period of 6 weeks 0 days to 7 weeks 6 days, only one significant plane could be obtained. At 8 to 10 weeks two to three sections were obtained, and after 11 weeks four, five, or even more sections could be produced through each scanning plane.

In the sagittal plane we obtained a lower number of scanning sections than in the coronal or axial planes because of the smaller transverse dimensions of the embryo-fetus.

The number of successful views in the three scanning planes (axial, coronal, sagittal) increased with gestational age. After the tenth week, almost all three of the scanning planes were obtained (Table III). The structures that were detected throughout each week of gestation from 6 to 14 weeks are detailed here.

6 weeks 0 to 6 days. Only one section through each plane was obtained. No brain structures were imaged. However, sections of the neural tube were seen on the coronal plane.

7 weeks 0 to 6 days. The telencephalic vesicle and mesencephalic vesicles were seen. On the axial and coronal planes, the myelocele was seen close to the end of this week.

8 weeks 0 to 6 days. In addition to the previous structures, the typical convoluted arrangement of the fetal brain in the sagittal plane becomes evident (Fig. 1A). The forebrain vesicles (telencephalic, diencephalic, and mesencephalic) were imaged. In addition to these, on the coronal section, the cerebral aqueduct, the metacoele (future fourth ventricle), and the myelocele (lower funneling of the fourth ventricle) were evident. On an axial section, the roof and cavity of the future rhombencephalon could be viewed. The posterior contours of the body were discernible. Fig. 1B enables comparison of the above-mentioned structures to drawings that depict the brain structures in question.

9 weeks 0 to 6 days. The outline of the ventricular system along the sagittal midline became clear (Fig. 2). The lateral telocoele (lateral ventricles) became distinct for the first time along with the sonographic markers of this age, the echogenic choroid plexi. In a few cases the thalami were seen. At this gestational age, multiple sections could be obtained.

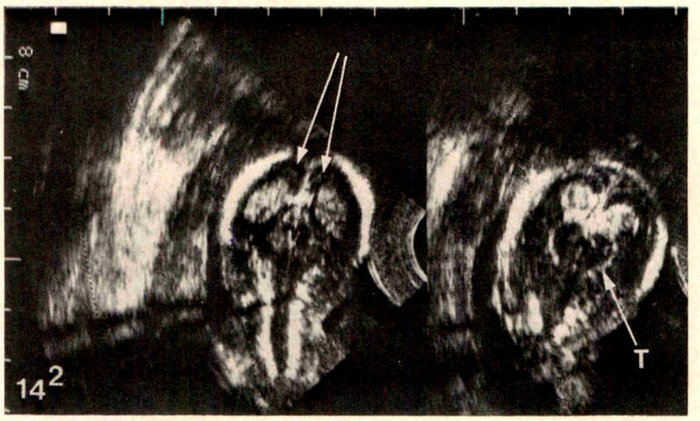

Fig. 7. Two successive coronal sections at 14 weeks 2 days. The left one is a posterior section that shows the choroid plexus filling the occipital horn of the lateral ventricles. A cortical mantle of 2 to 3 mm is now seen (marked by two *long arrows*). The section on the right shows the thalami *(T)*. The hyperechoic choroid plexi are on top of the thalami.

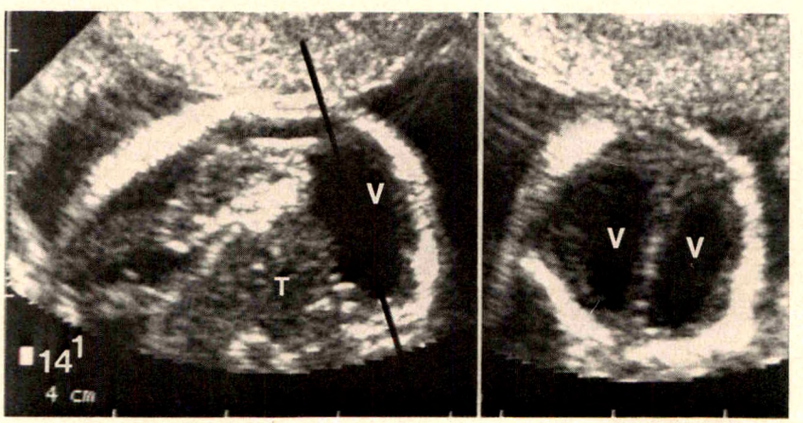

Fig. 8. A parasagittal section *(left)* through the brain at 14 weeks 1 day clearly shows the hyperechoic choroid plexus on top of the thalamus *(T)* which leaves a sonolucent frontal horn of the lateral ventricle *(V)* with ample "free space." The coronal section across the *black line* shows the typical frontal horns *(V)*.

10 and 11 weeks. The third and fourth ventricles could clearly be seen on the coronal section (Fig. 3). Clear choroid plexi were imaged on top of the thalami. Lateral ventricles with the choroid plexi and the cerebellum were seen on a small number of axial sections; close to the base of the skull the foramen magnum was consistently seen (Fig. 4).

12 weeks 0 to 6 days. The cerebellum, thalami, and eyes were better defined than previously. The third ventricle and choroid plexi were clearly defined (Fig. 5). The midline sagittal section showed for the last time the convoluted ventricular system (Fig. 6). The spinal contours were crisply outlined.

13 weeks 0 to 6 days. Only a few new structures were seen; however, the ones that were seen previously were increasingly better defined. The two layers of the falx cerebelli and falx cerebri could be seen. The larger sagittal and coronal venous drainage systems were seen. The choroid plexus "retracted" from the frontal horn and was shown to be predominantly located in the occipital horn (its final normal position). The cortical mantle and white matter are thick enough to be imaged the first time.

14 weeks 0 to 6 days. The structures that were seen previously were all imaged; however, their detection was easier. Since at this gestational age the size of the

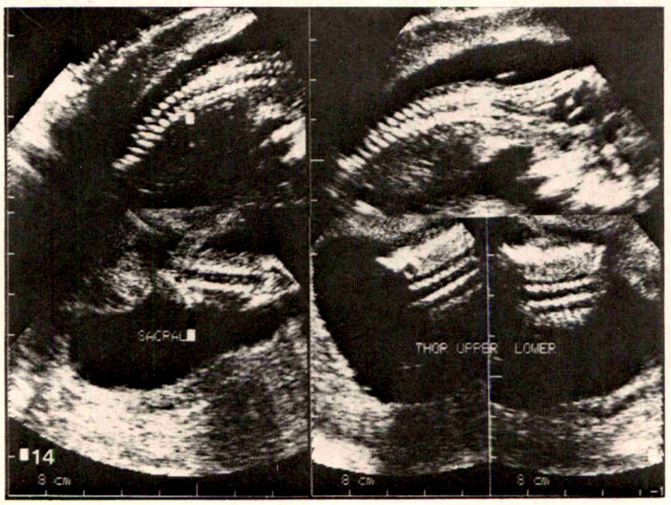

Fig. 9. Imaging of the spine in the sagittal plane and in several coronal sections is shown at 14 weeks.

fetus approaches the imaging limits of the vaginal probe, one had to apply a gentle fundal pressure to move the area of interest into the focal range of the probe. Spontaneous change of the fetal position was also helpful. The coronal sections were usually clear (Fig. 7). The frontal horns of the lateral ventricles displayed prominent sonolucent spaces, which were "free" of the choroid plexi (Fig. 8).

Comment

The number of practitioners who use transvaginal ultrasonography is constantly on the rise. If the crispness of the images that are created during the first and the early second trimesters is considered, it seems natural that this easily mastered scanning method will find its way into most obstetricians' offices. Whether in private offices or at tertiary centers, increasingly more ultrasonographers and physicians will be confronted by images similar to the ones presented in this study. The mean of the various sonolucencies and structures of the central nervous system has to be clear to everyone who is engaged in imaging of the fetus by transvaginal ultrasonography.

It is imperative that the normal ultrasonographically imaged central nervous system structure be well defined if clinicians are to use transvaginal ultrasonography for the workup of a 10-week-old to 14-week-old fetus for anomalies. The study that is presented here may form the partial basis for other such studies.

Several basic phenomena were revealed by this study. First, and probably the most imporant, was that an increasing number of central nervous system structures could be imaged with increasing gestational age. The second phenomenon was that these structures correspond perfectly to the already well-documented embryonic-fetal central nervous system structures that are depicted in available textbooks. Any person who engages in the ultrasonographic imaging of the embryonic-fetal central nervous system should scrutinize these atlases and textbooks to avoid misdiagnoses.

The third phenomenon was the ability to obtain an increasing number of sections ("slices") through any of the three classic scanning planes, as well as the fact that the number of possible sections increased with the gestational age.

We believe that, on the basis of this study, there is a possibility to detect maldevelopment of the central nervous system with reasonable accuracy in the late first and early second trimesters.

Endodermal sinus tumor of the ovary during pregnancy: A case report

A.G.J. van der Zee, MD,[a] H.W.A. de Bruijn, PhD,[a] J. Bouma, MD,[a] J.G. Aalders, MD,[a] J.W. Oosterhuis, MD,[c] and E.G.E. de Vries, MD[b]

Groningen, The Netherlands

Serum α-fetoprotein screening led to the detection of an endodermal sinus tumor of the ovary in a 24-year-old female in week 17 of pregnancy. After surgery, chemotherapy was postponed. In week 28 levels of serum α-fetoprotein increased, but delivery was delayed until 33 weeks' gestation. After delivery, the patient received four chemotherapy courses (cisplatin, etoposide, and bleomycin). Mother (24 months after last chemotherapy) and child are doing well. (Am J Obstet Gynecol 1991;164:504-6.)

Key words: Endodermal sinus tumor, pregnancy

Endodermal sinus tumor of the ovary is a rare, malignant germ cell tumor that primarily affects children and young women. The prognosis for these patients has improved since platinum-containing chemotherapy was added to surgery.

The association of endodermal sinus tumor and pregnancy is even more extraordinary. Knowledge of chemotherapy during pregnancy is growing, but limited data are available to determine the long-term risks for the in utero–exposed children. In this report we present a patient with endodermal sinus tumor diagnosed during pregnancy.

Case report

A 24-year-old woman in week 16 of her first pregnancy was screened for a neural tube defect of the fetus. The serum α-fetoprotein (AFP), measured with an enzyme-linked immunoassay (Abboth, Chicago), was elevated (22,000 ng/ml) (upper limit of normal at 16 weeks' gestation = 80 ng/ml). Serum human chorionic gonadotropin (hCG) level was normal.

Subfractionation of serum AFP, with concanavalin A crossed-line affinity immunoelectrophoresis, showed that 60% of the AFP was present in the nonbinding

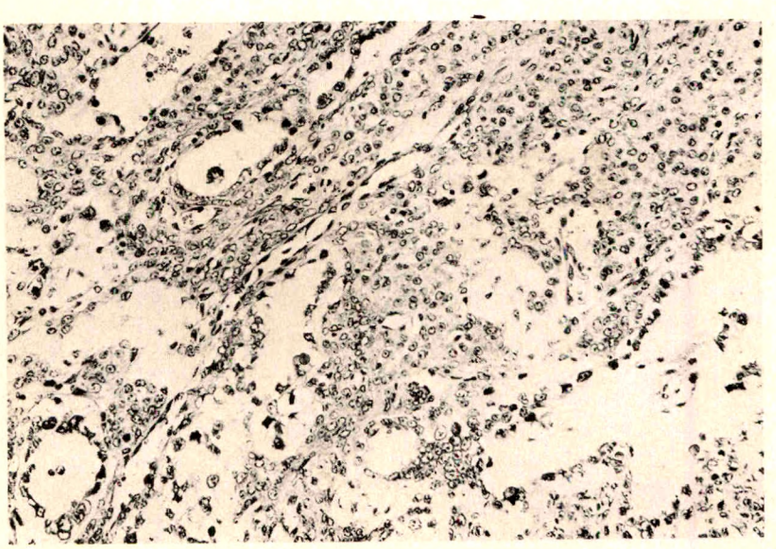

Fig. 1. Histology of endodermal sinus tumor, yolk sac tumor of ovary, with mixed histology including microcystic and alveolar glandular patterns (hematoxylin and eosin stain, × 140).

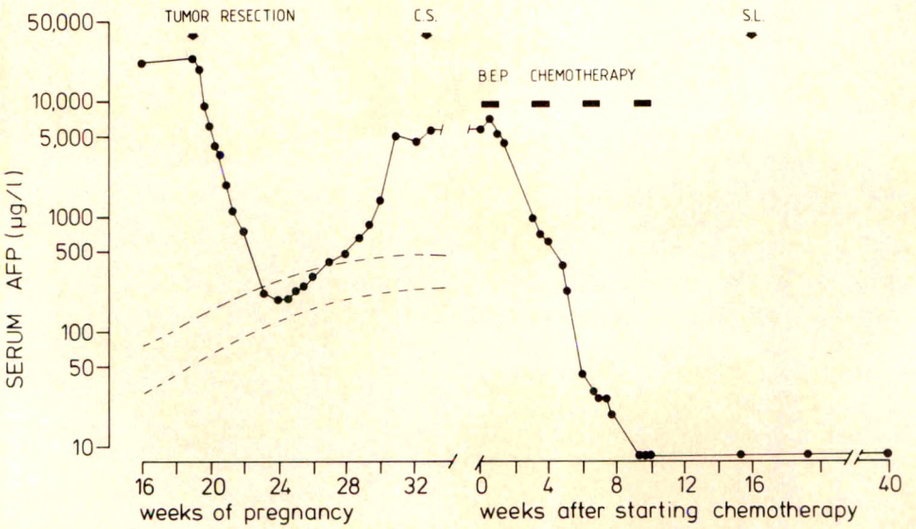

Fig. 2. Serum AFP profile during pregnancy and chemotherapy. *Dotted lines* represent median and 97th percentile as found during normal pregnancies. *Vertical arrows* indicate time at which laparotomies were performed. Courses of chemotherapy are indicated by *blocks*. *CS*, Cesarean section; *SL*, second look; *BEP*, cisplatin, etoposide, and bleomycin.

fraction. This is characteristic of AFP found in germ cell tumors.

At 18 weeks' gestation at rectovaginal examination a large pelvic mass was found. Ultrasonography showed a normal fetus and behind the uterus an irregular mass. The serum AFP level was now increased to 22,700 ng/ml. Laparotomy revealed a 10 × 12 cm tumor in the left ovary, adhesive in the cul de sac. The right ovary and the uterus were normal. No other tumor localizations were seen. Unilateral salpingo-oophorectomy was performed during which cystic fluid leakage occurred. A left pelvic lymphadenectomy and omentectomy were also performed.

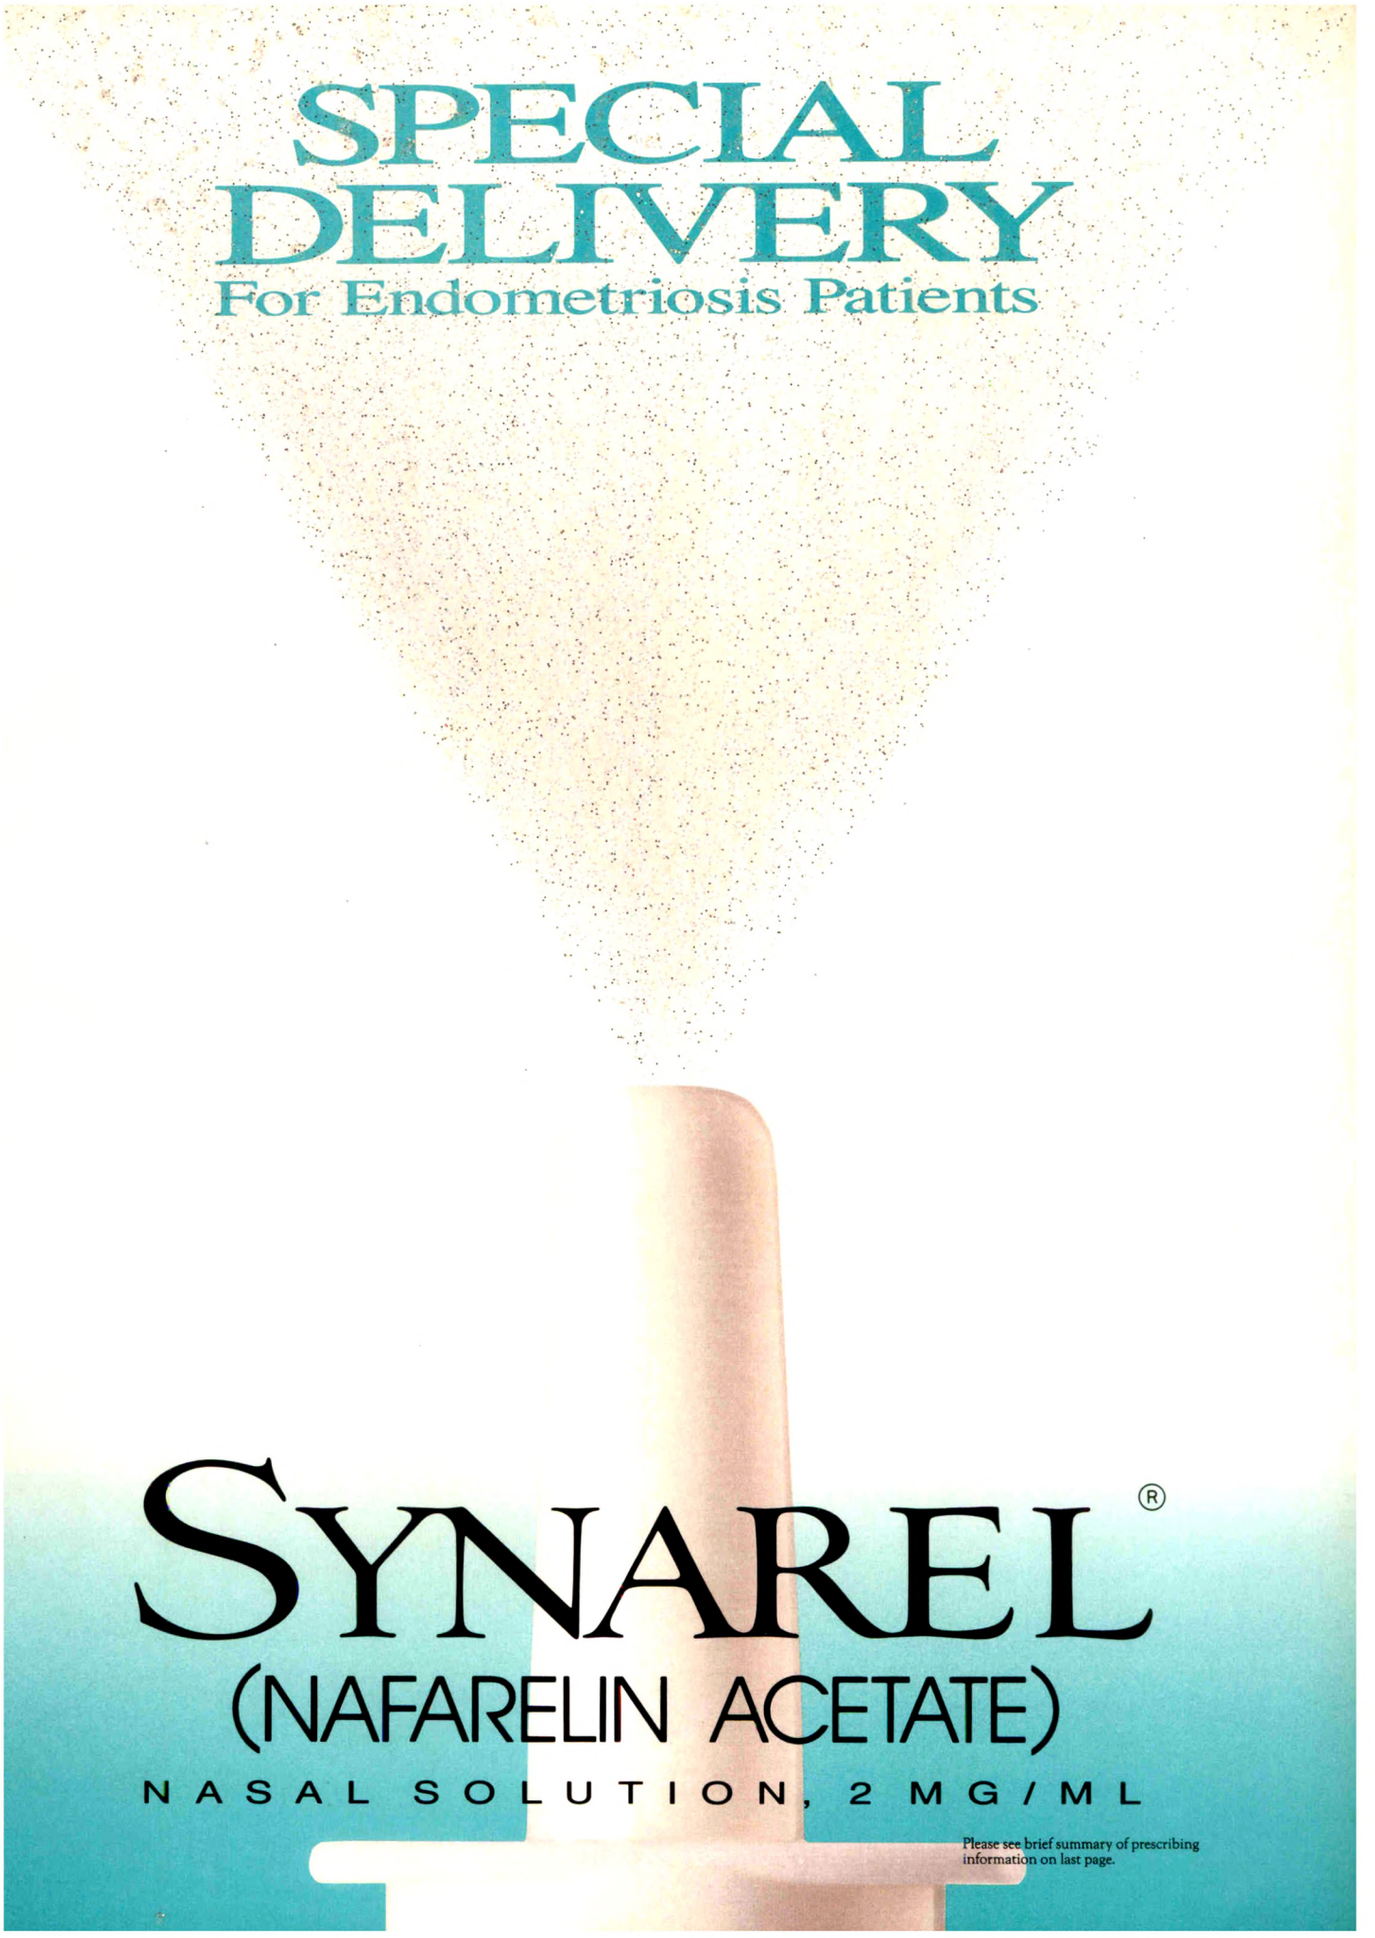
Final diagnosis was endodermal sinus tumor (Fig. 1) without evidence of metastatic disease. The first four weekly assayed serum AFP levels fell to normal for the duration of the pregnancy, but increased from 28 weeks' gestation onward (Fig. 2). After 5 weeks, at 33 weeks' gestation, characterized by an acceptable perinatal mortality and morbidity for the fetus, a male infant with body weight of 1990 gm and Apgar score after 3 minutes of 9 was delivered by cesarian section. Biopsy specimens from multiple tumor nodules seen in the pelvis, the paracolic regions, and on the diaphragm showed endodermal sinus tumor. The infant was admitted to the neonatal intensive care unit because of hyaline membrane disease that was successfully treated. Further development was undisturbed. At 6 days after surgery, chemotherapy was administered intravenously with cisplatin 20 mg/m^2 days 1 to 5 with prehydration and posthydration; etoposide 120 mg/m^2 days 1, 3, and 5; and bleomycin 30 mg days 2, 8, and 16. This cycle of 21 days was repeated four times. Bleomycin was withheld in the fourth cycle because of pulmonary toxicity. After two cycles serum AFP levels were normal (Fig. 2). Second-look laparotomy was performed after the last course of chemotherapy. Examination of the multiple biopsy specimens showed no residual disease. The patient was disease free 24 months after chemotherapy. The serum AFP and serum hCG levels have remained normal.

Comment

Currently, most physicians agree that, even in the eary stage, surgical treatment alone of a patient with endodermal sinus tumor is no longer justified. The results of surgery followed by platinum-containing combination chemotherapy are good, yielding a 70% to 90% overall rate of long-term survivors. The results of combination chemotherapy with cisplatin, etoposide, and bleomycin are comparable to those obtained with cisplatin, vinblastine sulfate, and bleomycin, but with less long-term toxicity.[1] Therefore, we decided to treat this patient with the cisplatin, etoposide, and bleomycin regimen.

Most of the scarce cases found in the literature were reported before the era of combination chemotherapy. Malone et al.[2] successfully treated one patient with endodermal sinus tumor in week 20 of pregnancy with surgery and two courses of cisplatin, vinblastine, and bleomycin before delivery and three courses after delivery. Metz et al.[3] treated one patient with an endodermal sinus tumor during pregnancy with surgery and five courses of vincristine sulfate, doxorubicin hydro-

chloride, and Cytoxan preparation of cyclophosphamide from 17 weeks' gestation. After delivery was induced at 37 weeks she received an additional seven courses. The outcome was successful for the mother and the child. Similar case reports have not been published.



To our knowledge, no specific data exist on the long-term effects of the administration of cisplatin-containing combination chemotherapy during pregnancy with regard to the child. The incidence of congenital anomalies after other various combinations of chemotherapy in the second and third trimester of pregnancy is reported not to be higher than that in uncomplicated pregnancies. However, almost no information is available to determine the long-term risks of in utero exposure to chemotherapy. These risks include development and growth disturbances, gonadal disorders, immunosuppression, and genetic and teratogenetic disorders in future generations. Because of the potential risks of this type of chemotherapy and the well-known efficacy of cisplatin-containing regimens, we avoided chemotherapy during pregnancy.

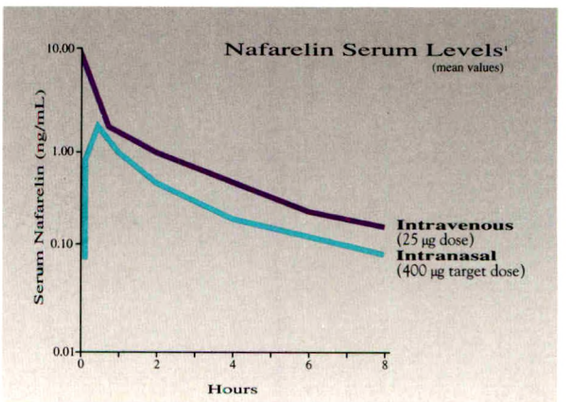
SPECIAL DELIVERY

For Endometriosis Patients

SYNAREL®

(NAFARELIN ACETATE)



NASAL SOLUTION, 2 MG/ML

Please see brief summary of prescribing information on last page.

The Only GnRH* Agonist With The Dosing Distinction Of Intranasal Delivery

- Intranasal administration produces nafarelin serum levels comparable to I.V. dosing: In pharmacokinetic studies, SYNAREL was rapidly absorbed into systemic circulation following intranasal administration, with maximum serum concentrations achieved between 10 and 40 minutes.[1]

- B.I.D. controlled-dose intranasal administration provides serum estradiol levels that result in outstanding clinical efficacy, while producing minimal impact on bone and a predictable hypoestrogenic profile.†
- Facilitates ease of patient management should allergic or other adverse events occur.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

1. Syntex document #829-223-A.

*Gonadotropin-releasing hormone analog.

†There is a small, largely reversible loss in bone density with 6-month treatment. Use of SYNAREL for longer than the recommended 6 months or in the presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a non-hormonal method of contraception when taking SYNAREL.

Please see adjacent page for brief summary of prescribing information.

SYNAREL®

(NAFARELIN ACETATE)

NASAL SOLUTION, 2 MG/ML

Setting The Pace In Endometriosis Therapy

SYNTEX *Committed to the OB/GYN and women's healthcare*

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

©1991 Syntex Laboratories, Inc.
829-H2-223-90

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.3% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 4.3% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Yes! Please begin my subscription to ***Current Problems in Obstetrics, Gynecology and Fertility*** (6 issues per year).

IN POSTPARTUM ENDOMETRITIS*

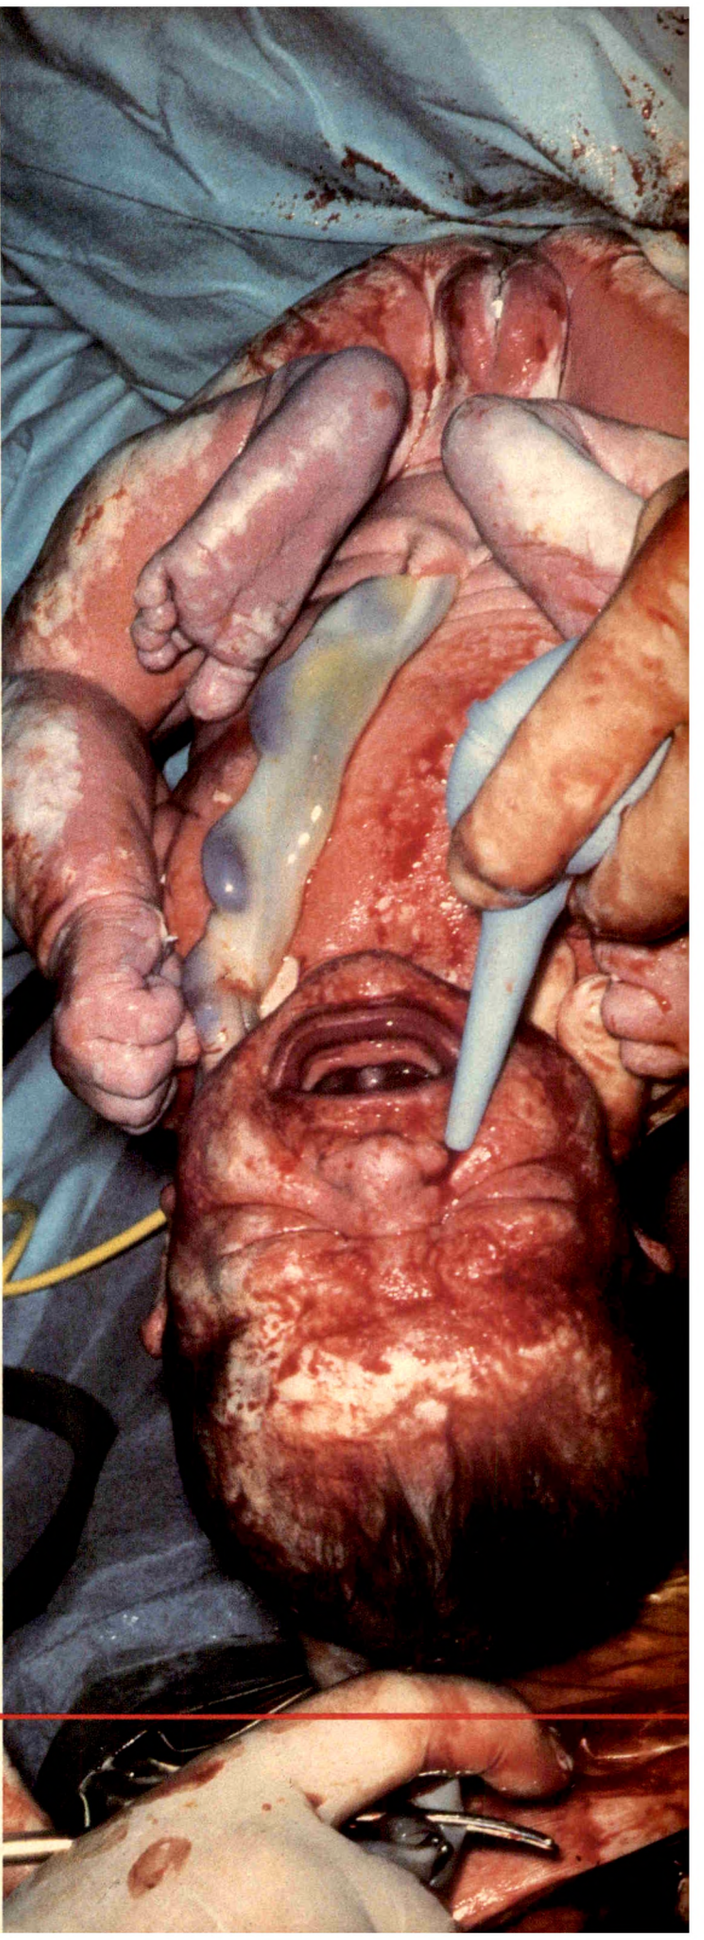
Azactam®
aztreonam
delivers...

A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.



‡Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.*†
- *Greater than 90% cure rates in combination with clindamycin.*[1-3]
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.*‡
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

Endothelial-derived relaxing factor released by endothelial cells of human umbilical vessels and its impairment in pregnancy-induced hypertension

Aldo Pinto, PhD,[a] Raffaella Sorrentino, PhD,[a] Paola Sorrentino, MD,[b] Teresa Guerritore, MD,[b] Lea Miranda, PhD,[a] Augusto Biondi, MD,[a] and Pasquale Martinelli, MD[b]

Naples, Italy

The principal objective of this study was to determine and compare the capability of human umbilical vessels of normal and pregnancy-induced hyperensive parturients to produce and to release the endothelial-derived relaxing factor. A bolus of bradykinin injected in the perfusion system of human umbilical vessels induces a release of a relaxant factor, detectable by bioassay, that is pharmacologically similar to the endothelial-derived relaxing factor. Human umbilical cords were collected from normal and pregnancy-induced hypertensive parturients. In the latter group the release of endothelial-derived relaxing factor is extremely reduced. In fact, in umbilical vessels collected from normal parturients, bradykinin at a dose of 20 pmol produces a release of endothelial-derived relaxing factor equivalent to a relaxation induced by 58.9 ± 11.0 and 30.8 ± 11.4 pmol of glyceryl trinitrate for the artery and vein, respectively. The same dose of bradykinin in umbilical vessels, collected from pregnancy-induced hypertensive parturients, produces a release equivalent to 6.6 ± 2.2 and 5.7 ± 3.5 pmol of glyceryl trinitrate equivalent for the artery and vein, respectively. Neither an increasing bolus of exogenous bradykinin or an infusion of superoxide dismutase or L-arginine was able to restore the production of endothelial-derived relaxing factor to normal levels. Our results indicate a probable alteration of endothelial cell numbers or an alteration of the enzymatic pathway, probably due to cytotoxic endogenous factors produced in pregnancy. (AM J OBSTET GYNECOL 1991;164:507-13.)

Key words: Endothelial-derived relaxing factor, human umbilical vessels, pregnancy-induced hypertension

Endothelial cells release a labile relaxing substance, named endothelial-derived relaxing factor (EDRF), that also shows antithrombotic properties[1] in response to a wide number of vasoactive agents,[2] including acetylcholine or bradykinin. Recently it has been proposed that EDRF, or one of its components, could be nitric oxide[3] that has been formed by metabolism of L-arginine.[4] It now appears clear that EDRF is involved in the maintenance of blood pressure[5] and that hypertension induced genetically or experimentally or by an alimentary method is accompanied by a reduction of the production and/or release of EDRF.[6-8]

Approximately 10% of complications in pregnancy are due to some degree to pregnancy-induced hypertension. This hypertension can produce severe perinatal morbidity and mortality.[9] At present the causes of this hypertension have not been identified, although concomitant changes in a number of factors have been shown.[10-13] Recently, several reports have documented biochemical abnormalities in serum from patients with preeclampsia, which support the concept that endothelial cell perturbation and sublethal injury of these cells may contribute to the pathogenesis of pregnancy-induced hypertension. Most of these studies have shown elevated levels of endothelial cell products in serum (for example, fibronectin[10] or factor VIII antigen[11]), with changes in hemostasis, an increase in corticotropin-releasing factor,[12] and a modification of the kallikrein-kinin and prostaglandin systems.[13] At the moment there is no evidence for endothelial damage on the fetal side of pregnancies complicated by hypertension. The purpose of this study was to assess the production and release of EDRF by human umbilical cord vessels and to assess if there is any variation of its production and release in pregnancy-induced hypertension.

Methods and material

Experimental technique. The technique used was a modification of that developed by Gryglewski et al.[14]

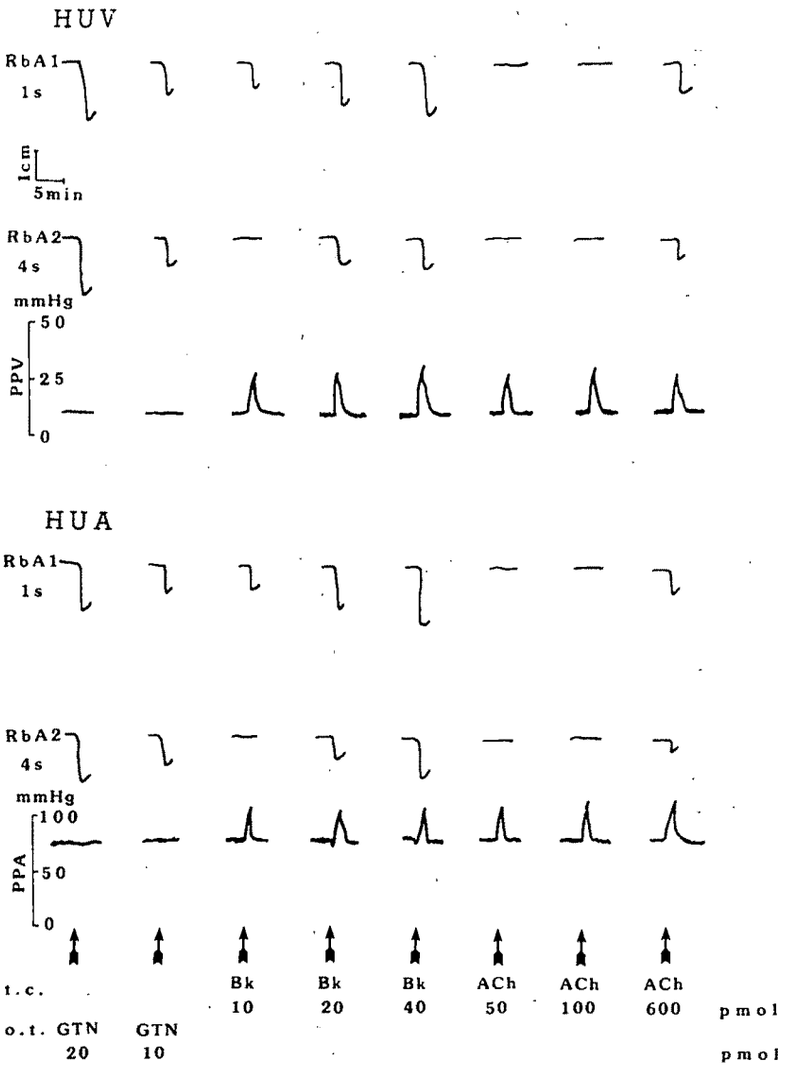

Fig. 1. Relaxation of strips of rabbit aorta by EDRF. The effluent of human umbilical vein *(HUV)* or artery *(HUA)*, from patients with normal pregnancy, perfused with Krebs buffer was used to superfuse two spiral strips of rabbit aorta which were separated from the umbilical vessel by delays of 1 second *(RbA1)* and 4 seconds *(RbA2)*, respectively. The tissues were contracted submaximally by a continuous infusion of phenylephrine (0.2 μmol/L). The sensitivity of the tissues was standardized with glyceryl trinitrate *(GTN)* administered over the tissues *(o.t.)*. The release of EDRF was stimulated by bolus injection through the cord *(t.c.)* of bradykinin *(Bk)* or acetylcholine *(ACh)*. Perfusion pressure for the artery *(PPA)* and the vein *(PPV)* was recorded.

and adapted to perfuse blood vessels.[15] The umbilical cords were collected from parturients after cesarean operation and immersed in Krebs bicarbonate solution with the following composition: sodium chloride, 118 mmol/L; potassium chloride, 4.7 mmol/L; calcium chloride, 2.5 mmol/L; magnesium sulfate, 1.2 mmol/L; potassium phosphate, 1.2 mmol/L; sodium bicarbonate, 25 mmol/L; glucose, 11.1 mmol/L. Ten-centimeter segments of human umbilical cord were taken and the umbilical vein or artery was cannulated at each end with polyethylene tubing and placed in a large organ bath containing gassed (95% oxygen plus 5% carbon dioxide) and warmed (37° C) Krebs solution. The vessel was perfused in the same direction of blood flow in vivo, with a flow rate of 2 ml/min of gassed Krebs solution at 37° C containing indomethacin (10 μmol/L). The perfusion in the artery started with a very low flow rate (0.250 ml/min) and gradually increased up to 2 ml/min when a steady state of perfusion pressure was reached to avoid a very high initial level of pressure. In the vein the perfusion started directly with a flow rate of 2 ml/min. The effluent from the

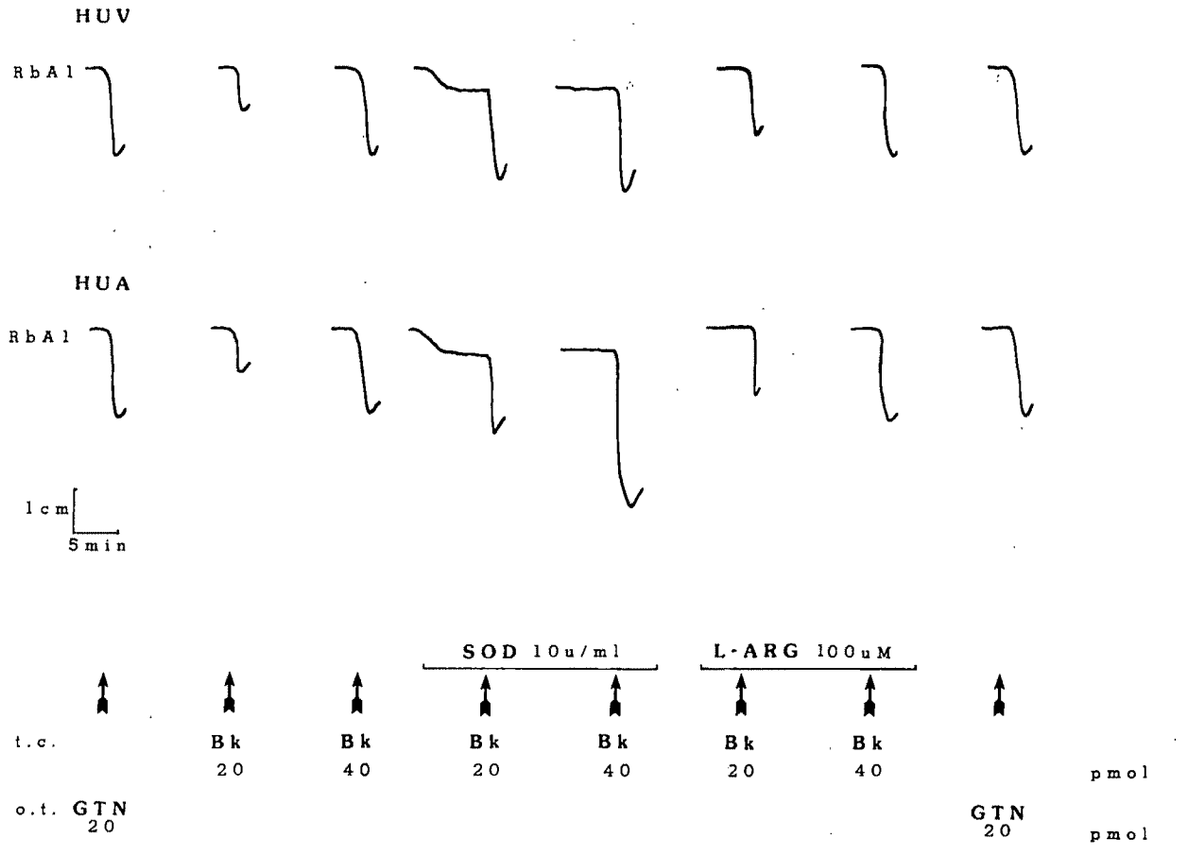

Fig. 2. Effect of superoxide dismutase *(SOD)* or L-arginine *(L-ARG)* on release of EDRF stimulated by bradykinin *(Bk)*. Effluent of human umbilical artery *(HUA)* or vein *(HUV)* of patients with normal pregnancy was used to superfuse spiral strip of rabbit aorta *(RbA1)* in a cascade. Glyceryl trinitrate *(GTN)* was used to test the reactivity of aorta strips.

vessel superfused a cascade of two spirally cut strips of rabbit thoracic aorta denuded of endothelium. The flow rate delay between the umbilical cord and consecutive first and second strips of rabbit thoracic aorta was 1 and 4 seconds, respectively. The bioassay tissues were contracted with a continuous infusion of phenylephrine hydrochloride (0.2 μmol/L over the tissues). Changes in the lengths of the bioassay tissues were monitored by isotonic transducers attached to a Gemini 7070 recorder (Basile, Lomerio, Italy). The sensitivity of the strips of rabbit thoracic aorta was adjusted so that they relaxed to a similar extent in response to a standard dose of glyceryl trinitrate. During all experiments the perfusion pressures of the umbilical vessels were monitored by a Statham pressure transducer. Human umbilical cords were collected after cesarean delivery of either normotensive pregnancy or pregnancy in which hypertension with proteinuria and edema (pregnancy-induced hypertension) occurred.

Patients. Patients were recruited from admissions to the Obstetrical Clinic of the Second Medical Faculty of Naples University. The diagnosis of pregnancy-induced hypertension was made on the basis of the criteria that systolic blood pressure was ≥140 mm Hg, diastolic pressure was ≥90 mm Hg, and proteinuria was ≥30 mg/dl with diffused edema to the limbs. The normotensive group contained patients who underwent cesarean delivery and had no alteration of blood pressure or any proteinuria or edema. None of the patients had a history of hypertension or renal disease before pregnancy. Subjects within the normotensive group did not undergo drug administration during pregnancy whereas the pregnancy-induced hypertension group were treated with antihypertensive agents, i.e., diuretics, methyldopa, β-adrenergic receptor antagonist or α_1-adrenergic receptor antagonists, but not with calcium channel blockers. The cesarean surgery was done at term pregnancy for the normotensive group and at 36.5 ± 1.5 weeks of gestation for the pregnancy-induced hypertension group.

Material. Phenylephrine hydrochloride, acetylcholine chloride, bradykinin, hemoglobin, L-arginine chloride, and superoxide dismutase were purchased from Sigma Chemical Co. (St. Louis). Glyceryl trinitrate (Ni-

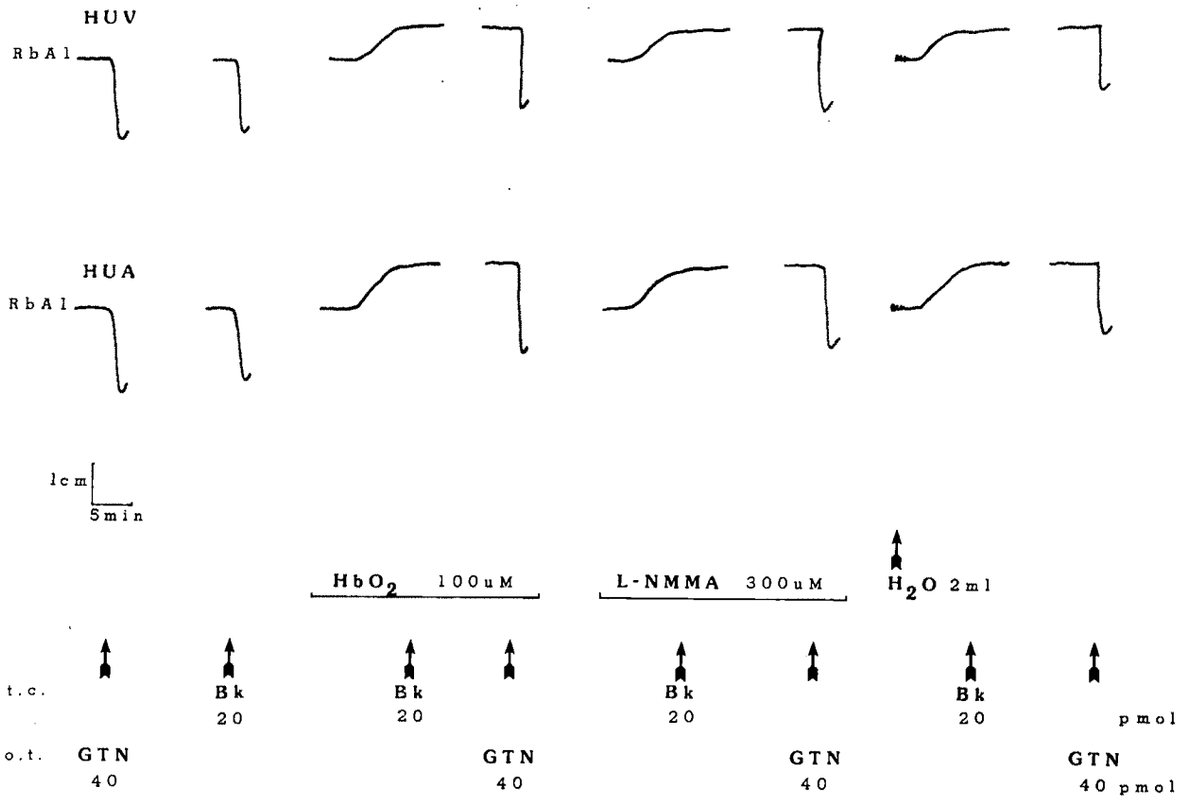

Fig. 3. Inhibitory effect of oxyhemoglobin *(HbO₂)* or L-N^G-monomethylarginine *(L-NMMA)* and destruction of endothelial cells by a flash of distilled water *(H_2O)* on release of EDRF stimulated by bradykinin *(Bk)*. Effluent of human umbilical artery *(HUA)* or vein *(HUV)* of patients with normal pregnancy was used to superfuse a rabbit aorta spiral strip *(RbA1)* in a cascade. Glyceryl trinitrate *(GTN)* was used to test the rabbit aorta strip reactivity.

tronal) was purchased from Lipha Pharmaceuticals Ltd. (Middlesex, United Kingdom). L-N^G-monomethyl arginine (Italfarmaco, Milan, Italy) was a gift from Dr. G. De Nucci. Oxyhemoglobin was prepared as described by Buga et al.[16]

Statistics. The amount of EDRF released was estimated in terms of relaxation of the bioassay tissues with glyceryl trinitrate used as standard, and results were expressed as picomoles of glyceryl trinitrate equivalent. Statistical analysis was performed with the two-way repeated measures analysis of variance test (two-tailed analysis), and a value of $p < 0.05$ was taken to be significant.

Results

Normotensive group. Bolus injection of acetylcholine or bradykinin through the umbilical artery or vein, but not over the tissues, produced release of a factor that was able to relax the precontracted strips of rabbit thoracic aorta (Fig. 1). Bradykinin was the more active substance in causing release of the relaxing factor from rabbit thoracic aorta strips, as compared with acetylcholine ($p = 0.001$). In fact, bradykinin in a dose range of 5 to 40 pmol ($n = 7$) produced a relaxation of rabbit thoracic aorta strip 1 equivalent to 10.7 ± 3.4 to 85.9 ± 7.9 pmol of glyceryl trinitrate, whereas only the highest dose of acetylcholine (600 pmol; $n = 5$) produced a small relaxation equivalent to 14.5 ± 4.5 pmol of glyceryl trinitrate. Between two administrations of acetylcholine or bradykinin we had to wait at least 30 minutes to have a repeated reproducible response. Since bradykinin was more active and reproducible, it was used in all the following experiments to characterize the nature of the factor.

To identify this bradykinin-induced relaxing factor as EDRF, we performed suitable experiments that produced these results:

1. The relaxation observed on rabbit thoracic aorta strip 1 declined during passage down the cascade on rabbit thoracic aorta strip 2 (Fig. 1). In contrast, the relaxation caused by glyceryl trinitrate did not decline (Figs. 1 and 2).

2. Infusion of superoxide dismutase (10 U/ml) or L-arginine (100 μmol/L) enhanced the release and/or production of the relaxing factor from both the vein and artery by about 3.5 times (Fig. 2). During superoxide dismutase infusion a decrease of basal tone induced by phenylephrine was observed.

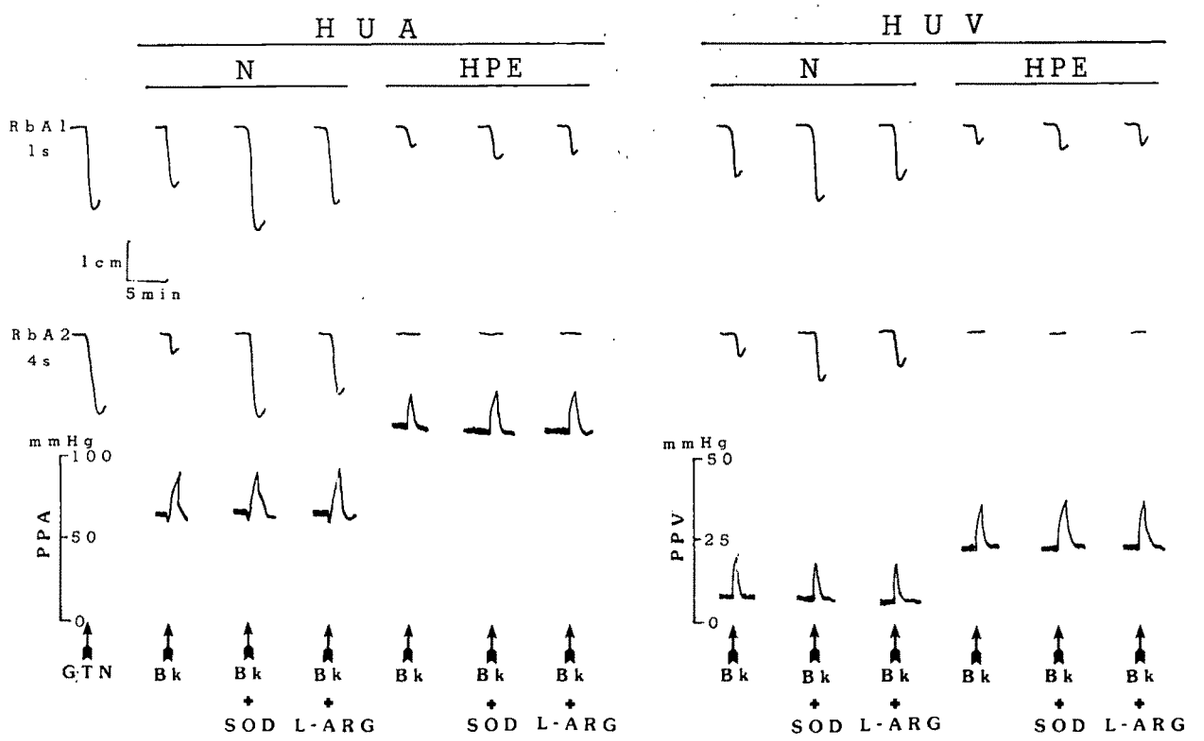

Fig. 4. Comparison between EDRF released from endothelial cells of human umbilical artery *(HUA)* or vein *(HUV)* of patients with normal pregnancy *(N)* and pregnancy-induced hypertension *(HPE)*. Bradykinin *(Bk)* was injected through the cord vessels in a bolus (20 pmol). There was a drastic reduction of EDRF production, and infusion of superoxide dismutase *(SOD,* 10 U/ml) or L-arginine *(L-ARG,* 100 μmol/L) was not able to restore normal production of EDRF in the *HPE* group. The reduction of EDRF released from *HUA* or *HUV* among the *HPE* group is associated with an increase of perfusion pressure of artery *(PPA)* and vein *(PPV)*. Glyceryl trinitrate, over the tissues, was used to test the reactivity of rabbit aorta strips (*RbA1* and *RbA2*) in cascade.

3. By destroying the endothelial cell monolayer with a bolus injection of distilled water (2 ml) or an infusion of oxyhemoglobin (100 μmol/L) or of L-N^G-monomethyl arginine (300 μmol/L), two inhibitors of EDRF formation, we observed a total disappearance of the relaxation produced by 20 pmol of bradykinin (Fig. 3). The flash of distilled water did not affect the smooth muscle functions of strips of rabbit thoracic aorta as shown by glyceryl trinitrate reactivity of the strips (Fig. 3) and the smooth muscle functions of the umbilical vessels as demonstrated by a sharp bradykinin-induced increase of perfusion pressure (data not shown). In addition, after a water flash or an infusion of inhibitors of EDRF production, there was an increase of basal tone of the strips of rabbit thoracic aorta by about 10% (Fig. 3). For the normotensive group the perfusion pressure in the artery, with an initial flow rate of 0.250 ml/min, started with 33.8 ± 9.9 mm Hg and declined to a steady, stable value of 12.5 ± 3.4 mm Hg in 7 to 10 minutes; then the flow rate was increased gradually by 0.250 ml/min at a time until a rate of 2 ml/min was reached and produced a steady, stable value of 71.4 ± 6.9 mm Hg. In the vein the flow rate of 2 ml/min produced a perfusion pressure of 50.3 ± 12.4 mm Hg that declined to a final pressure of 8.1 ± 1.3 mm Hg in 10 to 15 minutes. Bolus injection of bradykinin in the normotensive group produced a slight reduction of perfusion pressure immediately followed by a sharp, non-dose-dependent increase of pressure in the umbilical artery (Fig. 1). In the vein, in the same group, only the sharp, non-dose-dependent increase of pressure was observed.

Pregnancy-induced hypertension group. In the pregnancy-induced hypertension group bradykinin-induced EDRF release was reduced, as compared with that of the control (normotensive group) by 89.0% ± 10.4% (n = 5) in the artery and 81.4% ± 15.1% (n = 4) in the vein (Fig. 4 and Table I). In this group an infusion of superoxide dismutase or L-arginine produced an increase in the release and/or detection of EDRF but was not able to restore the amount detected to control levels (Fig. 4 and Table I).

For the pregnancy-induced hypertension group the perfusion pressure in the artery, with an initial flow rate of 0.250 ml/min, started with 65.2 ± 17.8 mm Hg that declined to a steady, stable value of 20.9 ± 7.5

Table I. EDRF expressed as picomoles of glyceryl trinitrate equivalent released by endothelium of human umbilical vessels from normal pregnancy and pregnancy-induced hypertension

Drug	*Dose*	*Artery*		*Vein*	
		Normal pregnancy	*Pregnancy-induced hypertension*	*Normal pregnancy*	*Pregnancy-induced hypertension*
Bradykinin	20 pmol	59.9 ± 11.0 (n = 7)	6.6 ± 2.2* (n = 5)	30.8 ± 11.4 (n = 7)	5.7 ± 3.5† (n = 4)
Bradykinin plus superoxide dismutase	20 pmol plus 10 U/ml	200.9 ± 54.6 (n = 6)	24.7 ± 9.7* (n = 4)	115.8 ± 37.1 (n = 6)	15.0 ± 6.2† (n = 4)
Bradykinin plus L-Arginine	20 pmol plus 100 μmol/L	114.8 ± 16.7 (n = 5)	15.8 ± 2.6* (n = 4)	44.5 ± 16.4 (n = 5)	13.1 ± 6.9† (n = 3)

Results are expressed as mean ± SEM.
*$p < 0.005$, pregnancy-induced hypertension versus normal pregnancy.
†$p < 0.05$, pregnancy-induced hypertension versus normal pregnancy.

Table II. Values of perfusion pressure for artery and vein of human umbilical cord of normal pregnancy and pregnancy-induced hypertension

Perfusion pressure	*Normal pregnancy*	*Pregnancy-induced hypertension*
Artery (mm Hg)	71.4 ± 6.9 (n = 9)	123.8 ± 30.5* (n = 6)
Vein (mm Hg)	8.1 ± 1.3 (n = 7)	21.6 ± 5.0* (n = 6)

Results are expressed as mean ± SEM.
*$p < 0.005$.

mm Hg in 10 to 15 minutes. Then the flow rate was increased gradually by 0.250 ml/min at a time until a rate of 2 ml/min was reached and produced a steady, stable value of 123.8 ± 30.5 mm Hg. In the vein the flow rate of 2 ml/min produced a perfusion pressure of 85.4 ± 15.7 mm Hg that declined to 21.6 ± 5.0 mm Hg in 10 to 15 minutes (Table II). Three umbilical cords from the pregnancy-induced hypertension group were discarded because they showed an initial perfusion pressure over 200 mm Hg. Also in umbilical vessels from pregnancy-induced hypertension group, the injection of a bradykinin bolus of 20 pmol produced a sharp, non-dose-dependent increase of perfusion pressure. However, the light reduction of perfusion pressure observed in the artery of the normotensive group, disappeared in the artery of the pregnancy-induced hypertension group.

Comment

Vascular endothelium generates an unstable vasodilator named EDRF.[2] Because of the lack of stability of EDRF in its physiologic environment (a half-life of about 6 seconds[14]), it can only be detected by biologic methods.

Umbilical vascular endothelium also generates prostacyclin and prostaglandin E_2.[15] The bioassay of EDRF is not influenced by the presence of prostacyclin or prostaglandin E_2 since neither of these two prostanoids affects the tone of the strips of rabbit thoracic aorta and the presence of indomethacin precludes the formation of prostanoids.

Bradykinin and acetylcholine are well characterized as inducers of EDRF release from almost all vascular endothelium. In this system, which uses the vessels of the human umbilical cord, the EDRF released in response to bradykinin and acetylcholine relaxed precontracted strips of rabbit thoracic aorta in a manner pharmacologically identical to that described for EDRF by several authors in mammals[2] and in human umbilical vessels.[16, 17] The relaxation is abolished after destruction of endothelial cells by a flash of distilled water and inhibited by oxyhemoglobin or L-N^G-monomethyl arginine.[4] Conversely, its detection increased by infusion of superoxide dismutase[18] or L-arginine.[4] Infusion of oxyhemoglobin or L-N^G-monomethyl arginine or a flash of water caused an increase in the contraction of the strips of rabbit thoracic aorta indicating a basal release of EDRF from the endothelium of human umbilical cord vessels, which was also confirmed by a decrease of the basal tone of strips of rabbit thoracic aorta observed with superoxide dismutase infusion. A further proof of the EDRF basal release was obtained with a double perfusion system: a direct superfusion line and a through-umbilical-vessel superfusion line. We observed a decrease of the basal tone of strips of rabbit thoracic aorta with the switch from a direct line to the umbilical vessel line (data not shown).

Bradykinin was more active than acetylcholine in releasing EDRF from human umbilical cord vessels, as was also observed by other authors.[17] This is possibly due to differences in the number of receptors present on the endothelium. It is interesting that there is an increase of plasmatic kininogen and urinary kallikrein in pregnancy and that infusion of bradykinin[13] or administration of kininase II inhibitor increases uterine blood flow.[19] Thus there is evidence to suggest a role

for bradykinin in the control of vascular tone and placental blood flow in pregnancy. This is further supported by experiments demonstrating that urinary kallikrein excretion falls to levels beneath those of a normal nonpregnant individual in patients in whom hypertension develops during pregnancy.[13]

A decrease in EDRF release has been observed in vitro in vessels of spontaneously[6] or experimentally[7] hypertensive animals, although the precise mechanism has not been established. In the anesthetized rabbit L-N^G-monomethyl arginine induces a dose-dependent, long-lasting increase in mean arterial blood pressure,[5] suggesting that a reduction in the synthesis of EDRF may contribute to the genesis of hypertension. These results are supported by our study, as there is a drastic reduction of bradykinin-induced EDRF release from the endothelium of human umbilical cord vessels collected from patients with pregnancy-induced hypertension and an increase in the perfusion pressure in both the artery and the vein. This could well be due to a reduction of the basal release of EDRF, also confirmed by the lack of reduction of the basal tone of strips of rabbit thoracic aorta with infusion of superoxide dismutase.

This reduction of EDRF production is not due to the decrease of circulating bradykinin or substrate (L-arginine) or to an increase of superoxide anions, because addition of exogenous bradykinin, L-arginine, or superoxide dismutase did not restore the detection of EDRF to normal levels. Possibly, then, there may be changes in the number of endothelial cells or in the enzymatic pathway of EDRF production within endothelial cells during pregnancy-induced hypertension.

The cause(s) of pregnancy-induced hypertension, the specific disease of pregnancy, is not yet clear because too many changes are involved in this pathologic condition (see Sullivan[13]). It is possible that the reduction of EDRF release from the umbilical vessels, which are structurally part of the fetal circulation, could reflect a decrease in EDRF release throughout the maternal circulation. The results of this study support such a hypothesis and are consistent with recent findings of a direct cytotoxic effect of serum from preeclampsia on cultured human endothelial cells of the umbilical vein, an effect that was markedly diminished post partum.[20, 21]

In conclusion, the presence of elevated serum endothelial cytotoxins and mitogens in prepartum sera from patients with preeclampsia could be consistent with these results of a reduction of EDRF release from the endothelium of umbilical vessels in pregnancy-induced hypertension and could support the hypothesis that endothelial injury is a major pathogenic factor in preeclampsia.

We are indebted to Dr. T. Warner and Dr. P. D'Orleans-Just of Williams Harvay Research Institute (London) for editorial assistance.

Prenatal records: A national survey of content

Mary D. Peoples-Sheps, DrPH, William D. Kalsbeek, PhD, Earl Siegel, MD, MPH, Cornelia Dewees, CNM, MN, Mary Rogers, MSN, and Robert Schwartz, MA
Chapel Hill, North Carolina

The uses of prenatal records extend well beyond management of patient care. They are also vehicles for communication, quality assurance, financial compensation, and legal documentation. To serve each of these functions, records should be systematic and detailed. This nationwide study was conducted to assess the extent to which prenatal records in current use include sufficient detail to serve these functions. A random sample of 2746 physicians who listed obstetrics and gynecology, obstetrics, or maternal-fetal medicine as a primary or secondary specialty in the American Medical Association file were contacted by mail and were requested to submit a blank copy of their prenatal records. The records of 969 respondents were examined for the presence or absence of 53 items that corresponded to the five functions identified above. The items of interest were present in 1% to 98% of the records. More than 90% included items of traditional medical-obstetric significance. The percentages of records with items of more contemporary relevance (e.g., cigarette smoking, risk-assessment checklists, psychological stress) were found in lower percentages of the records. Stratified and logistic regression analyses revealed that the most systematic and detailed records were commercially available, were used by physicians in hospital and government program-based practices, and were used by physicians who had completed medical school ≤15 years before the survey. The findings suggest that physicians who do not use commercially available forms or those who are in private or health maintenance organization practice or have been practicing for more than 15 years should reconsider their prenatal records in light of the functions they will serve in the 1990s and beyond. (Am J Obstet Gynecol 1991;164:514-21.)

Key words: Medical records, prenatal records, quality of medical records, uses of medical records

The demands placed on prenatal records in recent years are extensive and are becoming increasingly complex. In the past, these records were used primarily for the management of patient care, but today, prenatal records serve four additional major functions: communication, quality assurance, compensation, and documentation for legal purposes. Detailed information is required to perform these functions, although as Table I shows, different sets of information are required for each function.

Management of patient care. Prenatal records are considered major tools in the management of patient care. To serve this function effectively, they should include information in each of the nine categories shown in Table I.[1-3] Because there are many specific items that can be included in each category, records with detailed systematic formats have been developed. These formats are believed to enhance the content of care by prompting providers to include elements of prenatal surveillance and intervention that might otherwise be omitted.

Communication. Effective communication among maternity care providers and among service facilities is essential to the appropriate management of patient care. The prenatal record is the major vehicle for this communication, and all the nine types of information shown in Table I are required to serve this function. Because prenatal records are the primary tools for transmitting information to providers in inpatient facilities, it is especially important that they include space to document the involvement of other elements of the health care system, such as hospitalization during the prenatal period and referral to other health care providers. This information provides a comprehensive picture of the care received.

Quality assurance. Prenatal medical records are also important in monitoring compliance with standards for patient care. The records are particularly useful for this purpose if patients' problems, the processes of care, and corresponding results are systematically documented. The Professional Standards Review Organizations and other peer review and quality assurance groups rely on medical records to assess these param-

Other diagnostic procedures	x	x	x	x	x
Therapeutic procedures	x	x	x	x	x

eters.[2-4] For example, screening for sexually transmitted diseases during pregnancy is a standard of care that can be evaluated from information in this record. The reviewer should be able to determine whether testing was performed, the results of testing, whether patients with positive tests were identified and treated, and whether a test of cure was performed. Record formats that include space for the documentation of repeated laboratory testing and for medical treatment encourage recording the necessary information.

Compensation for services. Prenatal records provide documentation for out-of-pocket and third-party billing. This function is becoming increasingly important, inasmuch as Medicaid and some other insurers are "unbundling" maternity services. Under this framework, services are reimbursed by visit according to the content and complexity of care, rather than at a standard fee for a maternity care package. Thus accurate and complete documentation of patient complications and of services provided is essential for full reimbursement.

Documentation for legal purposes. The traditional functions served by prenatal records have been overshadowed in recent years by medicolegal functions. Appropriate documentation of health problems and interventions is an essential component of a provider's response to an obstetric malpractice suit. The frequency of these lawsuits has increased, and the need for clear documentation to show that adequate care was given has become more compelling. As shown in Table I, the types of information required for documentation for legal purposes are the same as those required for quality assurance. The record should show that risk factors and complications were properly identified, and that the course of pregnancy was managed in an appropriate manner.[5]

To be useful, prenatal records should be problem-oriented, systematic, and sufficiently detailed. Some formats, such as checklists for risk assessment and flow charts to detail the results of each physical assessment, have been developed to make information easily available. At least two problem-oriented maternity record systems are commercially available.[6,7] Other record systems have been developed for internal use by private providers and agencies,[8,9] and the American College of Obstetricians and Gynecologists has developed a brief prenatal record that became available late in 1989.[10]

The availability of systematic prenatal records and the important patient care, communication, quality assurance, compensation, and legal rationales for using systematic records argue in favor of widespread use. Until this study, however, actual levels of use were unknown. The purpose of this study is to assess the extent to which systematic and detailed maternity records are used by providers of prenatal care.

Material and methods

The sample for the study consisted of 2746 physicians who had been selected at random from a master file maintained for the American Medical Association. The file is considered virtually complete.[11] In this article, the term "physician" is used for both medical doctors and for doctors of osteopathy. The original sample of 2746 included 2656 medical doctors and 90 doctors of osteopathy. The sample of 969 analyzed in this article included 940 medical doctors and 29 doctors of osteopathy. Only physicians who were practicing at the time of the study and who listed obstetrics and gynecology, obstetrics, or maternal-fetal medicine as a primary or secondary specialty were eligible for inclusion. Systematic sampling after a random start from a list ordered by the zip code for the address of the physician's practice was used as the selection method.

A survey packet that included a cover letter, a brief questionnaire, and a prepaid business reply envelope was mailed to each selected physician. The cover letter explained the purpose of the study and requested that

respondents send us a blank copy of one complete prenatal record and the completed questionnaire in the prepaid envelope. The questionnaires were designed to obtain some basic practice and demographic data from respondents.

A pretest was conducted on 10% (276) of the sample in March 1987. The instruments and procedures were then revised slightly, and the main survey was started in May 1987. A reminder letter was sent 3 weeks after the initial mailing to those who had not responded.

Response rates for the survey are shown in Table II. A total of 54.4% of physicians responded and blank prenatal records were submitted by 38.0%. Table II also shows the distribution of physician responses by primary specialty and geographic region as defined by the first digit of the zip code for the physician's mailing address. Response rates differed across groupings; for this reason, weights were created to adjust for the variation.

Each record was reviewed for the presence or absence of 53 specific items or groups of items. These items were selected because they represent each of the essential types of record information listed in Table I. Efforts were made to select a set of items that showed a balance between traditional and more contemporary relevance to prenatal care. Hence, emphasis was given to items such as patient education, smoking, and other behaviors, as well as to more traditional medical and obstetric items. For an item to be coded "present," an unambiguous label for that item had to be in the record. A space to write conditions or procedures without the specified label was not sufficient for a code of "present."

From the original set of 53 items and indictors (i.e., groups of items), we selected 10 for in-depth analysis. These items were present in 11% to 89% of the records and were considered a representative subset of the original 53. They are the dependent variables defined in the appendix.

The appendix also includes definitions of five independent variables that were used in both stratified and logistic regression analysis. Three of the variables (primary specialty, type of practice, and number of years since graduation from medical school) were collected from respondents on the survey questionnaire. Location of the practice was determined from the first digit of the zip code. Type of prenatal record was ascertained from the record itself.

Cutoff points for each of these dichotomous independent variables were based on hypothetic grounds because there has been little research in this area. The cutoff points for two of the variables (type of practice and location) may not be intuitively obvious. Initially, health maintenance organization (HMO) practices (n = 47) were grouped with hospital and government program-based practices. However, preliminary analyses suggested that the presence of items in records of HMO physicians was more consistent with those of private physicians than those of hospital or government program-based physicians. Thus HMOs were grouped with private practices. With regard to location, the decision to include the Northeast and California in one group and the rest of the country in the other was based on the hypothesis that areas with numerous prenatal care services and large medical complexes would be more likely to have comprehensive prenatal records, primarily as a result of more rapid dissemination of new information, peer pressure, and geographic ease of oversight.

All reported findings from the survey reflect the design and weighting adjustments that were made to compensate for differential nonresponse. The data were adjusted by a weighting class procedure that used primary specialty and geographic region to define the adjustment cells.[12] Two statistical programs were used. The standard errors program for computing of standardized rates from sample survey data (SESUDAAN)[13] computer software package enabled us to estimate the percentage of records with items present, and a logistic regression (RTILOGIT)[14] was used to estimate coefficients for the assumed logistic regression program for analysis of survey data models used to identify predictors of the presence of certain items in the records.

Results

In Table III, distributions of selected characteristics of the 969 respondents who submitted prenatal records are presented. Almost 90% of the respondents specialized in obstetrics and gynecology, obstetrics, or maternal-fetal medicine, and a similar percentage was in either solo private practice or group private practice. A total of 40% had completed basic professional training 15 or fewer years before the survey. With regard to geographic region, there was considerable variation, which ranged from 5.5% in areas with zip codes starting with 5 to 19.8% where 9 was the first digit of the zip code. Finally, almost half of these respondents submitted a prenatal record that was not developed by one of the commercial producers [Problem-oriented perinatal risk assessment system (POPRAS) or Hollister] or by a hospital, health department, or government program.

Table IV contains estimates of the percentage of physicians' records with the 53 prenatal care items or item groups described earlier. The half-widths of 95% confidence intervals reported parenthetically indicate (in percentage points) the likely error due to sampling in these estimates. Percentage estimates range from 1% to 98%. The items that were present in >90% of the records were of traditional medical-obstetric significance, including such items as date of last menstrual period, description of previous pregnancies, and flow chart with standard items. At the opposite end of the spectrum are many items that have been recognized as relevant only in recent years. Indicators of psychological and financial stress, of a change in consumption of cigarettes, and of chlamydia test results, for example, were found in <10% of the records. However, it is important to note that even some widely accepted prenatal practices did not have clearly identifiable labels. A space to record the indication for ultrasonography was present in only 10% of the records, and 4% included an entry for prenatal hospitalizations.

Table V shows weighted estimates of the percentages of prenatal records with the 10 items selected for further analysis (dependent variables) by five of the characteristics of respondents (independent variables). Several trends are apparent in Table V.

All the POPRAS and Hollister records included eight of the items. The smoking and drinking items were present in 89% of those records because POPRAS records did not include them until the 1985 revision. In striking contrast to POPRAS and Hollister, none of the items was in >60% of records developed by others. Items found in <20% of the records developed by others were the quantity of cigarettes smoked and the checklist items such as entries for intrauterine growth retardation, sexually transmitted diseases, and for assigning prenatal risk status. Spaces to document general patient education, nutritional assessment, and demographics were available in 20% to 30% of the records of the other group.

In Table V, no percentages of other independent variables were smaller than 22 or greater than 80, and differences between categories tended to be smaller than in the type of record comparison. Differences in percentages by primary specialty and geographic region tended to be quite small.

More variation was found across categories of type of practice and number of years since graduation from

*1985 and 1987 POPRAS records included this item; earlier versions did not.

†95% Half-widths were computed as 1.96 times the SE of the estimated percentage of records with the item or indicator present.

medical school. Physicians who were engaged in private or HMO practices used substantially fewer records with each of the items of interest. Similarly, smaller percentages of records of physicians who finished medical school more than 15 years before the survey included the items when compared with those of physicians who had been practicing for 15 or fewer years.

Each of the items in Table V was analyzed in a series of logistic regression models with physician specialty group, the type of practice in which the physician was engaged, the number of years in practice, and the geographic location of the practice as independent variables. The type of prenatal record was not generally useful for this analysis because, except for quantity of cigarettes smoked and use of alcohol, all the physicians who used Hollister and POPRAS standardized forms had the items present. Because of the colinearity created by the type of prenatal record, the coefficients with the type of prenatal record present are little different from those with the type of prenatal record absent. This analysis was thus done on the subset of respondents (84.2%) who did not use the POPRAS or Hollister forms.

Our analysis strategy was to subject all 10 items to the same models. We first examined predictive equations with both main and interaction effects present. This approach afforded us the most direct comparison of the predictive nature of the independent variables among dependent variables as it clarified the relatively minor role of higher-order interaction effects. For the 10 models that involved the 4 independent variables previously listed, only 3 of 60 first-order interaction coefficients were statistically significant (at the $p < 0.05$ level).

Findings for the main effects models presented in Table VI generally confirm our earlier descriptive findings. The type of practice was clearly important statistically because coefficients for the type of practice were found to be significant in 7 of 10 models. The negative sign in each case indicates that, with other independent effects constant, those physicians in HMOs and in private practice were relatively less likely to have labeled spaces for recording these items than were physicians in other types of practices.

All but two coefficients for the number of years since medical school were positive, and three of them (use of alcohol, checklist with intrauterine growth retarda-

tion, and use of medications) were statistically significant (at the $p < 0.05$ level). This suggests that physicians who were recent graduates (≤15 years) were more likely to use records with entries for behavioral and other risks. For each of the remaining independent variables (specialty and location) only one coefficient was significant. Physicians who did not list obstetrics and gynecology as a primary specialty used significantly more records with checklists that included an entry for sexually transmitted diseases. Those in the Northeast and in California used more records with entries for alcohol use. Otherwise, specialty and location were not strongly related to the dependent variables.

Comment

Despite compelling reasons for using detailed systematic records in prenatal care, the results of this national survey show that such records are not in widespread use. Most of the records in this sample included items of traditional medical and obstetric significance, the recording of which contributes to the essential functions of prenatal records (Table I). In general, however, the level of detail in the records did not adequately reflect the emergence of new information about risks of adverse pregnancy outcomes or newer technologies for prenatal surveillance and diagnosis of problems.

The commercially available POPRAS and Hollister records included virtually all the items of interest, although some respondents were using older POPRAS forms that did not include the smoking and drinking items required for this analysis. The availability of entries in the records developed by others varied greatly. It is important to note, however, that some of the records in the "other" group were detailed and systematic, as shown by the results of logistic regression analysis, which excluded respondents who used POPRAS and Hollister forms.

Logistic regression analysis also showed that the physicians who were more likely to have detailed record items were in hospital and government program-based practices and were recent (≤15 years) graduates of medical schools. Medical schools are, of course, the locations of many hospital-based practices.

The types of prenatal record entries that were found deficient in our study were also identified in the Newborn Neurologic Deficit Study (Localio AR and Siegel JE. Unpublished data.). In their analysis of 591 claims involving allegations of neurologic deficit caused by negligent medical care for deliveries, the investigators found that only 15% reported information on alcohol consumption and that 27% reported smoking history. They also observed that whereas prenatal diagnostic tests and procedures were better documented, the results were frequently unavailable. In an effort to apply a simplified risk scoring system, they found that data on at least one risk factor were missing in 45% of the cases. From a legal perspective, these deficiencies, which are highly consistent with the ones we found, leave practitioners extremely vulnerable in the event of malpractice litigation.

Item deficiencies also undermine the ability of prenatal records to serve other functions adequately. In a less complicated time, when a single physician provided continuous care to his or her patients, simple records with adequate space for comments were probably sufficient. Many of the records we received had ample space for "write-ins." Without clear labels, however, the information necessary for adequate patient care in the 1990s, which includes billing, quality assurance, and communication within and among health care systems, may or may not be recorded.

On the other hand, it cannot be assumed that the presence of labeled spaces in a medical record will assure that the requested entries are made. Incomplete and misleading entries in medical records have been documented repeatedly,[15, 16] and the correlation between good reporting and good care remains controversial.[15] However, without specific labels and adequate detail, the extent to which recording may be incomplete is difficult to assess. The purpose of the systematic de-

sign of problem-oriented medical records is to promote completeness and to reduce ambiguity in medical recordings.[17] The POPRAS and Hollister forms, as well as many of the records developed by hospitals and government programs, are based on the problem-oriented medical record model. As indicated, the American College of Obstetricians and Gynecologists has recently begun to distribute a new systematic record.[10] Most of the record is organized as a checklist with space for comments. Special emphasis has been given to linking diagnostic tests to procedures with corresponding results and interpretations. Whereas the form does not include all of the items examined in this study, it does include most of them, and its four-page format may be attractive to busy practitioners.

Physicians in private practice (solo or group), those associated with HMOs, and those who have been practicing for more than 15 years may wish to review the adequacy of their records with regard to the functions that prenatal records should serve, the results of this study, and the options for detailed systematic records that are available to them.

We thank Carol J.R. Hogue, PhD, for consultation during the course of this study, and Kenneth V. Heland, JD, for reviewing an early draft of the manuscript. The expert skills of Susan Harris also are very much appreciated.

Appendix

Definitions of items from the National Prenatal Records Survey

Item	*Description (categories used for logistic regression analysis)*
Dependent variables (1 = item present in record, 0 = item not present)	
DEMO	Basic minimum sociodemographic data (i.e., age, race, education, and marital status)
DRINK	Space to indicate alcohol use in present pregnancy
SMOKE	Indication of the quantity of cigarettes smoked
USIZE	Space to record uterine size at first prenatal visit
NUTR	Space to indicate that a nutritional assessment was done
EDUC	Space to document general patient education
IUGR	Checklist of complications of present pregnancy with an entry for intrauterine growth retardation
STD	Checklist of complications of present pregnancy with an entry for sexually transmitted diseases
RISK	Checklist for the purpose of risk assessment
MEDIC	Space for recording medications used in current pregnancy
Independent variables	
FORM	Type of prenatal record (1 = POPRAS/Hollister standardized form, 0 = other)
SPECIALTY	Physician's primary specialty (1 = obstetrics and gynecology, 0 = other)
PRACTICE	Type of physician practice (1 = private solo or group, HMO, 0 = other)
YEARS	Number of years since graduation from medical school (1 = ≤15 years, 0 = >15 years)
LOCATION	Region of the country as determined by the first digit of the zip code for the address of the physician's practice (1 = first digit of 0, 1, or 9 for the Northeast and California; 0 = other)

Reproductive factors and risk of endometrial cancer

Fabio Parazzini, MD,[a] Carlo La Vecchia, MD,[a, b] Eva Negri, ScD,[a] Luigi Fedele, MD,[c] and Fulvia Balotta, MD[a]

Milan, Italy, and Lausanne, Switzerland

The role of reproductive factors in endometrial cancer risk has been analyzed in a case-control study conducted since 1983 in the greater Milan area on 568 women (cases) with histologically confirmed endometrial cancer and 1925 women (controls) who were admitted for acute, nonmalignant, hormonal, gynecologic conditions to hospitals that cover a comparable catchment area. Compared with nulliparous women, parous women had a 30% lower risk of endometrial cancer, but there was no evidence of a decline in risk with increasing number of births. The risk of the disease decreased with number of spontaneous or induced abortions; the multivariate relative risk estimates were, compared respectively with no spontaneous or induced abortions, 0.5 for women with two or more spontaneous abortions and 0.3 for women with two or more induced abortions; both trends in risk were statistically significant. When parous women only were considered, no association emerged between endometrial cancer and age at first birth, but the risk decreased with increasing age at last birth: compared with women whose last birth occurred before age 25, the relative risk was 0.5 for women who were ≥35 years old at last birth, and the multivariate trend in risk was statistically significant. For most of the reproductive factors that were considered, the risk estimates tended to be greater at younger age or among premenopausal women and to flatten off in subsequent strata of age. An association between endometrial cancer and age at first birth was observed in women who were ≤49 years old, but not in older groups. The observation that later age at last birth as well as later first birth in younger women decreases the risk of endometrial cancer suggests a short-term protective effect of pregnancy. This finding is consistent with a late-stage (promotional) effect of reproductive factors on endometrial carcinogenesis. (Am J Obstet Gynecol 1991;164:522-7.)

Key words: Endometrial cancer, reproductive factors

Reports from different countries have suggested that infertile or nulliparous women are at increased risk of endometrial cancer. The potential protective role of each single birth or total number of births is, however, largely controversial.[1-12] For example, a decreasing trend in risk of endometrial cancer with increasing number of term pregnancies was observed in two case-control studies conducted in the United States[4, 5] and in a cohort study in Norway[10] but not in a previous analysis of our Italian data set[6] and in an American case-control study.[1] Furthermore, the extent of protection, if any, of incomplete pregnancies (i.e., spontaneous or induced abortions) is unclear.[2, 5, 10] Recently a Norwegian cohort study[10] and a Scandinavian population-based case-control study[9] have shown that endometrial cancer was more frequent in women of early age at first and last birth, which suggests that the relation between parity and risk of endometrial cancer shares a more complex hormonal mechanism than infertility. We have further considered the relation between reproductive factors and the risk of endometrial cancer with data from a large case-control study that was conducted in Italy.

Patients and methods

In the framework of a general surveillance of breast and gynecologic malignancies, since 1983 we have been conducting a hospital-based case-control study of endometrial cancer in the greater Milan area.[6, 13, 14]

The cases that were studied were 568 women below the age of 75 (range, 28 to 74 years; median, 61 years) with histologically confirmed endometrial cancer that was diagnosed within the year that preceded the interview who had been admitted to the National Cancer Institute and to the Ospedale Maggiore (which includes the four largest teaching and general hospitals in the greater Milan area).

Controls were women who were admitted because of acute conditions to several specialized university clinics or to the Ospedale Maggiore of Milan. They were admitted because of diseases that were not malignant,

hormonal, or gynecologic in origin and/or that were judged to be unrelated to any of the identified or suggested risk factors for endometrial cancer. They had not undergone hysterectomy and/or bilateral oophorectomy. A total of 1925 controls, aged 25 to 74 (median age, 54), were interviewed; of those, 32% were admitted because of traumatic conditions (mostly fractures and sprains), 25% had nontraumatic orthopedic disorders (mostly low back pain and disc disorders), 15% had conditions that required surgery (mostly abdominal, such as acute appendicitis or strangulated hernia), and 28% had other illnesses, such as ear, nose and throat or teeth disorders. Less than 2% of the identified cases and controls refused to be interviewed.

Information was collected by trained interviewers with a standard questionnaire on personal characteristics and habits, gynecologic data, number of births, number of spontaneous and induced abortions, age at first and last births, relevant medical history, and history of lifetime use of female hormones. The present report is based on data that were collected up to December 1988.

Data analysis. Odds ratios (as estimators of relative risks) of endometrial cancer together with their 95% approximate confidence intervals were first computed from data stratified in 5-year intervals of age by the Mantel-Haenszel procedure.[15] When a factor could be classified in more than two levels, the significance of the linear trend was assessed by the test described by Mantel.[16] Relative risks were then determined after simultaneous allowance for potential confounding effects of age (in single years), education, marital status, menopausal status, body mass index, estrogen replacement therapy, hypertension, diabetes, and, in turn, parity, number of induced and spontaneous abortions, and age at first and last birth through unconditional multiple logistic regression equations that were fitted by the method of maximum likelihood.[17]

Results

The distribution of cases and controls according to age, education, marital status, menopausal status, body mass index, and use of estrogen replacement therapy is presented in Table I. The control group was consistently younger than the case group (median age, 54 vs 61 years), which reflects the criteria of selection within this case-control surveillance that covers simultaneously several gynecologic neoplasms. Furthermore, women with endometrial cancer tended to be less educated and more frequently overweight, and they reported more frequent use of estrogen replacement therapy.

Overall, compared with nulliparous women, parous women had a 30% lower risk of endometrial cancer. The multivariate point estimate was of borderline statistical significance. There was no evidence, however, of a decline in risk with increasing number of births, and the test for trend was not statistically significant (Table II). The risk of cancer of the corpus uteri decreased with number of spontaneous or induced abor-

tions; the relative risk estimates compared respectively with no spontaneous or induced abortions, were 0.6 for women with two or more spontaneous abortions and 0.3 for women with two or more induced abortions. Both trends in risk were statistically significant.

When parous women only were considered, no significant association emerged between endometrial cancer and age at first birth. Compared with women whose first birth occurred before the age of 25, the relative risks were 1.1 for women 25 to 29 years old and 0.7 for women ≥30 years old. In contrast, the risk of the disease decreased with increasing age at last birth: compared with women whose last birth occurred before the age of 25, the multivariate relative risks were 0.7 for women 25 to 29 years old, 0.6 for women 30 to 34 years old, and 0.5 for women ≥35 years old. The multivariate relative risks for various reproductive variables were largely similar to the Mantel-Haenszel estimates, which were adjusted for age only (Table II).

The role of reproductive factors was further examined in strata of menopausal status (Table III). Compared with nulliparous women, the risk in parous women was 0.3 (95% confidence interval = 0.1 to 0.6) before menopause and 0.8 (95% confidence interval = 0.6 to 1.2) after menopause. Spontaneous and induced abortions and age at last birth were inversely related with the risk of cancer of the corpus uteri in premenopausal and postmenopausal women, but these inverse associations tended to be systematically stronger in premenopausal women. The relative risk for two or more miscarriages, for instance, was 0.3 before menopause and 0.5 after menopause, and relative risk for

last birth at age ≥35 was 0.3 before menopause and 0.6 after menopause.

Corresponding analyses in subsequent strata of age (<50, 50 to 59, and ≥60) are presented in Table IV. For various reproductive factors that were considered, the associations tended to be stronger at younger ages and to flatten off in following strata of age, even after allowance for menopausal status by means of multivariate analysis. For instance, the relative risks for parous versus nulliparous women were 0.3, 0.6, and 0.8 in the three age groups that were considered.

An association between endometrial cancer and age at first birth was observed in women ≤49 years old (compared with women who had first birth at ≤24 years old, the multivariate relative risk estimates were 0.6 and 0.4 for women 25 to 29 years old and ≥30 years old) but not in older subgroups. Likewise, in younger women the risk of endometrial cancer decreased with late age at last birth, but this association tended to flatten off in subsequent strata of age.

Comment

This large data set provides more precise information than has been previously available on the role of reproductive factors in endometrial carcinogenesis. A reduction in risk (of borderline significance) was observed in parous women, but there was no evidence for the risk to decline with increasing numbers of births. Spontaneous or induced abortions and late age at last birth appear to protect against endometrial cancer. These effects were more evident in premenopausal women. Late age at first birth was associated with a

lower risk of cancer of the corpus uteri in women ≤49 years old, but the relation tended to flatten off in older women. Thus age or menopausal status appeared to have an important modifying effect on the relation between reproductive factors and risk of endometrial cancer.

Selection should not present a major problem in this study, since cases and controls were identified in institutions that cover broadly comparable catchment areas and since participation was almost complete. Likewise, information bias can hardly have a role on variables like parity or age at births. In relation to confounding, strict allowance for single year, as well as simultaneous allowance for several potential distorting factors, including body mass index, measures of social class, or marital status, did not appreciably change the risks for any of the reproductive factors that were considered. The role of reproductive variables should be considered in the framework of the unopposed estrogen hypothesis in endometrial carcinogenesis,[18] which postulates that any factors that increase esposure of endometrium to unopposed estrogen increase the risk of the disease. Conversely, anything that increases progesterone levels would lower the risk.[18-20]

Pregnancy reduces the time of exposure to unopposed estrogens and this may explain the higher risk in nulliparous women. However, in our study the protective effect of parity seems to be largely restricted to the first term pregnancy; the risk estimates are comparable in subsequent strata of number of births. This suggests that infertility and not parity per se should be associated with the risk of endometrial cancer. Infertility can be related to anovulation, which is characterized by long-term unopposed estrogenic menstrual cycles.[18, 21]

The hypothesis that infertility is a risk factor for endometrial cancer is supported by studies that show a higher risk for married nulliparous women than for unmarried ones.[2] Furthermore, two case-control studies and a cohort study that were conducted in the United States found an increased risk of endometrial cancer in women who reported infertility prob-

lems.[5, 7, 22] In a cohort study of infertile women, however, there was no overall increased incidence of endometrial cancer, although the risk was apparently elevated in women <50 years old or in the first 20 years after evaluation.[23] In the latter study, the risk was still greater in women with progesterone deficiency.

Few studies have analyzed the relation between incomplete pregnancies and risk of endometrial cancer, and the findings are largely inconsistent.[2, 5, 10] In our study, the risk of the disease was significantly lower in women who reported one or more spontaneous or induced abortions. This can be interpreted in terms of differential fertility between endometrial cancer cases and controls. The decreasing trend in risk that was observed with increasing numbers of abortions could be tentatively viewed in terms of higher fertility in women who required induced abortions or who reported more frequent miscarriages, among which a certain proportion of induced abortions may possibly be misclassified.

The finding that the effect of nulliparity is more evident in premenopausal women and the significant inverse association with age at last birth that was found in this case-control study, as well as in a prospective study that was conducted in northern Europe,[10] suggest that the protective effect of pregnancy is greater in the short term after birth. This is consistent with the pattern of risk in infertile women in the Mayo Clinic cohort.[23] Along this line, we have found that later age at first birth decreased the risk in younger women (i.e., up to one or two decades after pregnancy) and that this effect tended to flatten off in subsequent age groups. Within the framework of the multistage theory of carcinogenesis,[24] this is consistent with a late-stage (promotional) effect of these reproductive factors, which is similar to that observed for estrogen replacement treatment.[18] This again confirms that the biologic mechanisms for the action of these reproductive factors is probably mediated through changed hormonal balances and thus contributes to a unifying interpretation of the role of various risk factors for endometrial carcinogenesis.

Cervical findings in rape victims

Laura Slaughter, MD and Carl R.V. Brown, PhD
San Luis Obispo, California

The difficulty of documenting genital findings in rape victims by gross visualization is well known. However, we report two cases in which cervical findings were readily established by colposcopic examination and photography. Use of the colposcope may significantly increase the reliability of establishing findings in rape victims. (Am J Obstet Gynecol 1991;164:528-9.)

Key words: Physical findings, rape; cervical trauma, sexual assault

Obtaining corroborative physical data from rape victims is a difficult task. Previously published literature documents only a 10% to 30% rate of positive physical findings in such cases.[1, 2] This dismal result has prompted some authors to suggest that the performance of a genital examination be reserved for those who complain of pain or have a history of undergoing instrumentation.[2] However, with the magnification made possible by using the colposcope, we report two cases in which cervical findings were documented and discuss their medical and forensic significance.

Case reports

Case 1. A 17-year-old female was invited by a friend to his room in a fraternity house. There he immobilized her on his bed and put his fingers into her vagina and began "jabbing her." She began crying; he eventually stopped and allowed her to leave. A physical examination was performed 5 days after the incident. With the colposcope, punctate areas of hemorrhage were seen on the hymen at 5 and 7 o'clock with the patient in a supine position. Cervical examination showed fine linear abrasions just below the cervical os (Fig. 1). Menstrual blood was noted. Reevaluation in 5 weeks showed complete healing of these injuries.

Case 2. A 30-year-old woman presented to the emergency room with complaints of lower abdominal pain and scanty vaginal bleeding. Approximately 2 hours earlier, she had been attacked by an unknown man while walking on the beach. After pinning her down, he stuck what "felt like a knife" into her vagina. Genital examination showed blood at the introitus. A linear laceration was noted on the right in the vaginal barrel, and the cervix showed several punctate and linear lacerations (Fig. 2). These were completely healed by the time of her follow-up examination in 4 days.

Comment

The medical literature to date establishes that genital examination in rape victims yields results in 10% to 30% of cases. This information is based on examination by means of gross visualization alone. In contrast, applying the advanced technology afforded by the colposcope, our group was able to see and photograph trauma to the victim's cervix. This type of injury has not been previously reported. These two cases illustrate how trauma can be reliably documented via colposcopic magnification; in both, the pattern of injury is inconsistent with blunt force or penile penetration. Moreover, documentation of the healing process is an important part of the forensic assessment. First, it links the traumatic event to the injuries observed, establish-

Fig. 2. Multiple puncture wounds and fine linear lacerations on superior surface of cervix.

ing a time frame reliably associated with injury. Second, documentation of the victim's normal anatomy in the follow-up examination effectively establishes her as her own control against which the court can evaluate the nature, extent, and cause of the injury. This is particularly important when the body parts injured are not ones commonly seen. Neither of these patients needed treatment, and thus the injuries may be considered trivial from a purely medical viewpoint. Legally, the information obtained from these examinations is significant. The data here support vaginal penetration, which is basic to a charge of rape. In addition, it can also substantiate the use of a foreign object,* which is a separate crime and thus offers an enhancement in charging and sentencing procedures.

The physician who examines rape victims must provide not only medical and psychological support to the victim but also forensic information to the legal authorities. This information must include evidence of vaginal penetration and physical findings consistent with the history and timing given by the victim. Protocols to examine victims of sexual assault might be revised to include colposcopy to more reliably document genital injuries and their resolution.

We gratefully acknowledge the efforts of Jane Kulick, RN, and the San Luis Obispo County Suspected Abuse Response Team and express our appreciation for the support of San Luis Obispo General Hospital and Sexual Assault Victim Education.

*Rape with a foreign object is defined by the California Penal Code as vaginal penetration with anything other than a penis.

Continuous electrocardiographic monitoring in hypertensive crises in pregnancy

Datshana P. Naidoo, MD, Ismail Bhorat, MD, Jack Moodley, MD, Janardana K. Naidoo, MD, and Abdul S. Mitha, MD

Durban, South Africa

Twenty-four patients first seen with hypertensive crises during pregnancy were studied by continuous electrocardiographic monitoring for a period of 24 hours to detect the presence of serious ventricular arrhythmias. Three patients were excluded from analysis because of low serum potassium levels. Thirteen of the remaining 21 patients had ventricular tachycardia on subsequent analysis of the electrocardiogram. These arrhythmias subsided after induction of anesthesia when blood pressure control was optimal. This finding may be implicated in the pathogenesis of pulmonary edema and sudden death in these patients. (AM J OBSTET GYNECOL 1991;164:530-3.)

Key words: Arrhythmia, hypertension, pregnancy

Eclampsia is the leading cause of maternal mortality at large referral centers throughout the world.[1] In 1987 seven of 34 maternal deaths at the King Edward VIII Hospital in Durban, South Africa, were caused by eclampsia. Although cerebral hemorrhage does cause a significant number of these deaths, a proportion of them are unexplained. Furthermore, pulmonary edema is a recognized complication in patients with hypertensive crises of pregnancy and contributes to increased mortality in these patients.[2] The possibility that unexplained sudden death and pulmonary edema may be related to serious cardiac arrythmias has not been investigated. The aim of this study was to detect the presence of malignant ventricular arrhythmia in patients with hypertensive crises of pregnancy.

Material and methods

Selection criteria. The study group comprised 24 patients in whom the diagnoses of eclampsia and imminent eclampsia were made. Eclampsia was defined as convulsions associated with hypertension and proteinuria. A diagnosis of imminent eclampsia was made in patients with hypertension, proteinuria, and symptoms of imminent eclampsia (i.e., epigastric pain, blurring of vision, headache, and cerebral irritability).[3] All patients were managed by standard procedures described elsewhere.[4] This included central venous pressure monitoring, lowering of blood pressure with intravenous hydralazine hydrochloride, diazepam to terminate seizure, and magnesium sulfate to prevent further convulsions. The time of administration of specific drug therapy including those used during anesthesia were recorded. In patients who required cesarean section a standard regimen of drug administration was used. This included intravenous administration of lidocaine (100 mg) to suppress a hypertensive response during intubation.[4]

On entry into the study, a full clinical examination was performed and blood samples were taken for measurement of serum potassium, magnesium, and calcium. An arterial blood sample was obtained for blood gas analysis and radiography of the chest was performed. Continuous electrocardiographic monitoring was then instituted for a period of 24 hours to include the predelivery, delivery, and immediate postdelivery periods. Recording was performed with a four-channel Holter recorder (Spacelab 7200, Redmond, Washington) and the full recording was printed for analysis. Arrhythmia detection and analysis were performed on a Holter analysis computer (Spacelab 90101). Results were confirmed by visual inspection of the complete recording and ventricular extrasystoles (premature ventricular contraction) were analyzed by the modified Lown grading system.[5] The grading system assigns premature beats into one of the following categories: grade 0, not a single premature ventricular contraction in 24 hours; grade I, occasional premature ventricular contractions; grade II, frequent premature ventricular contractions (>30 per hour or 1 per minute); grade III, multiform premature ventricular contractions;

grade IVA, couplets; grade IVB, runs of three or more in succession (ventricular tachycardia).

Control readings were obtained in normotensive primigravid women in the last trimester of pregnancy. Three patients with low serum potassium levels were excluded from analysis. In the remaining patients serum biochemistry and blood gas values were within normal limits. The mean age in both study and control groups was 22 years. Inasmuch as most of the patients with imminent eclampsia–eclampsia syndrome arrive at the hospital early, the mean period of gestation in the study group was 32 weeks (control = 38 weeks). Sixteen patients in the study group and eight in the control group were delivered of infants by cesarean section. The remainder were delivered vaginally.

For statistical purposes each grade was assigned a numeric score that ranged from 1 (grade 0) to 6 (grade IVB). Both the frequency of premature ventricular contractions and grade of arrhythmia was compared in the predelivery and delivery phases and in the delivery and postdelivery phases (Wilcoxon signed-rank test). The grade of arrhythmia was compared with mean arterial pressure with the nonparametric Mann-Whitney U test.

Results

In the study group the mean of the systolic, diastolic, and mean arterial pressures on admission were 174, 120, and 138 mm Hg, respectively (control group: 110, 70, and 83 mm Hg, respectively). Precordial examination was normal in both groups. A third heart sound was heard in three patients in the study group. Cardiomegaly was not a feature in any of these patients. Three patients who had crepitations at the lung bases exhibited pulmonary edema on chest radiography. Central venous pressure was raised to 16 cm water in these three patients.

Arrhythmias occurred in five patients in the control group and consisted of occasional, isolated ventricular extrasystoles (Lown grade I). Arrhythmias occurred in all patients in the study group. Six patients showed occasional ventricular extrasystoles (Lown grade I). In the remaining 15 patients ventricular extrasystoles were frequent (>30 per hour) but because of complex arrythmias, all fell into a higher grade (Lown grades III and IV). Thirteen patients had ventricular tachycardia (Lown grade IVB) and in only two of these was the arrhythmia not sustained beyond 10 beats. In four patients the run lasted for at least 30 beats. In all instances ventricular tachycardia was self-limiting. The mean arterial pressure in the patients with ventricular tachycardia was significantly higher than that in the remaining patients ($p = 0.0003$) (Fig. 1). All three patients

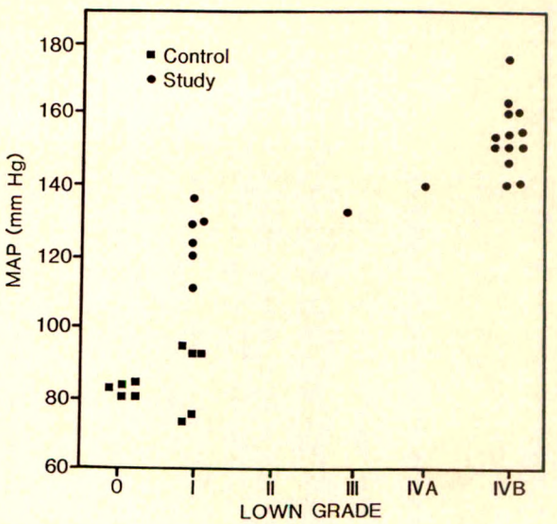

Fig. 1. Grade of arrhythmia versus mean arterial pressure (*MAP*).

with pulmonary edema exhibited ventricular tachycardia on the electrocardiogram (Fig. 2).

Both the incidence of premature ventricular contractions and the Lown grade fell during the delivery phase in 15 patients (71%) and rose immediately thereafter (Figs. 3 and 4). Fourteen of these patients were delivered of infants by cesarean section after general anesthesia was induced. Four of the five patients who were delivered vaginally had high grade arrhythmias (Lown grade IV) that did not abate during delivery. In all patients arrhythmias eventually abated when blood pressure normalized (8 to 12 hours after uterine evacuation).

Comment

This study shows that malignant ventricular arrhythmias occured in 15 of 21 patients with hypertensive crises of pregnancy (71%). These arrhythmias were not related to electrolyte imbalance, deranged acid-base status, or hypoxia. Pulmonary congestion and edema developed in three of the 15 patients with malignant arrhythmias despite a normal precordial assessment. The development of pulmonary edema identifies a high-risk subset of patients and is associated with increased maternal morbidity and mortality.[2]

Several mechanisms have been postulated to explain the pathogenesis of pulmonary edema in these patients including hypervolemia[6] (fluid infusion), pulmonary capillary leakage,[6, 7] and left ventricular failure.[6] Hemodynamic studies have documented raised levels of cardiac output with no evidence of myocardial depression.[8, 9] However, the generalized arterial vasospasm

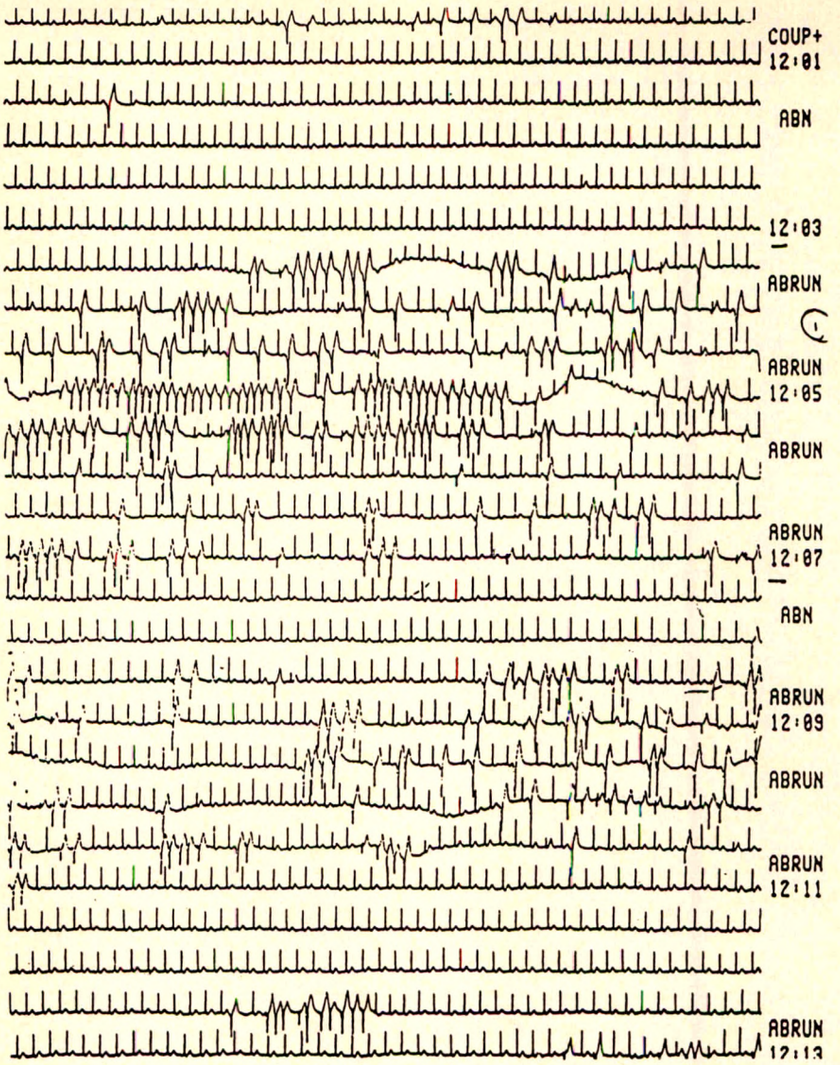

Fig. 2. Sample strip of electrocardiogram with ventricular tachycardia (Lown grade IVB). Patient had pulmonary edema.

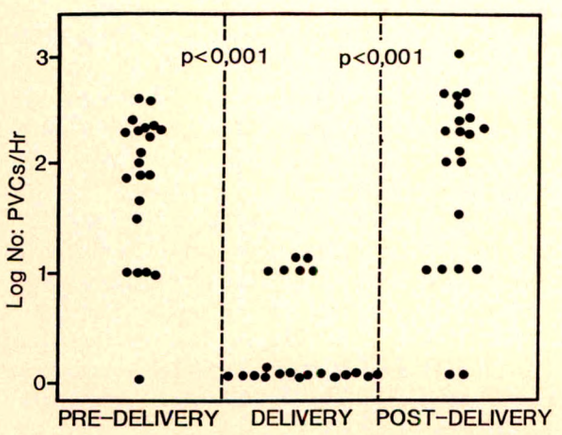

Fig. 3. Frequency of premature ventricular contractions *(PVCs)* per hour in different periodsof delivery.

that is known to be present results in markedly elevated systemic resistance with an increase in stroke work and thereby transient left ventricular dysfunction.[10] In the setting of increased afterload the high frequency of ventricular tachycardia noted in this series provides a more plausible explanation of the development of pulmonary edema and sudden death in these patients.

It appears that a relationship exists between the severity of hypertension and the presence of arrhythmia in patients with hypertensive crises of pregnancy. During the intrapartum phase there was a decrease not only in the frequency of premature ventricular contractions but also the grade of arrhythmia. This was attributed to the mode of delivery. Most of the patients were delivered of infants by cesarean section after induction of general anesthesia. During this period oxygen was administered, blood pressure control was op-

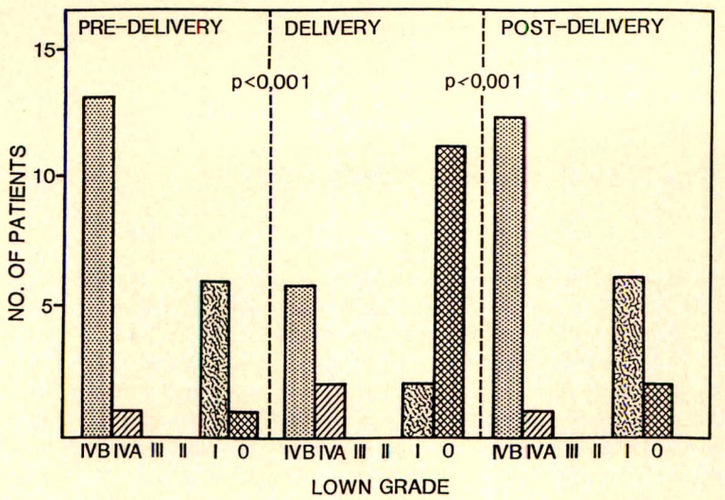

Fig. 4. Grade of arrhythmia in different periods of delivery.

timal, and lidocaine (1 mg/kg) was administered during induction to suppress the hypertensive response to intubation. All three factors probably contributed significantly to control of the arrhythmia. In the five patients who were delivered vaginally lidocaine was not used and so may explain the fact that in these patients the arrhythmias persisted during the intrapartum phase.

The pathogenesis of these arrhythmias is uncertain. Increased ventricular ectopic activity has been seen in patients with essential hypertension when compared with normotensive subjects. However, ventricular arrhythmias were noted to be more prevalent in patients with left ventricular hypertrophy.[11, 12] This does not appear to be the case in patients with hypertensive crises of pregnancy in whom the hypertension was acute and transient. Previous studies showed raised levels of catecholamines in maternal blood collected during labor and after delivery in pregnancies complicated by severe preeclampsia.[13] This may contribute to myocardial necrosis and ventricular irritability. With the generalized vasospasm that occurs in eclampsia, coronary perfusion may also be compromised.[14] Thus the outpouring of catecholamines with resultant tachycardia and elevated systemic vascular resistance could contribute to increased left ventricular stroke work and myocardial ischemia.

This study has practical implications in the management of hypertensive crises of pregnancy. The use of agents that lower blood pressure together with antiarrhythmic properties may be beneficial in the prevention of pulmonary edema and sudden death. The role of β-blockers, the safety of which has been attested in pregnancy.[15] needs to be explored in future studies.

In conclusion, complex ventricular arrhythmias are common in patients with hypertensive crises of pregnancy. This could be a contributory factor in the pathogenesis of acute pulmonary edema and sudden death in these patients.

Umbilical artery blood flow velocity waveforms during variable decelerations of the fetal heart rate

Erich Weiss, MD, Thomas Hitschold, MD, and Peter Berle, MD
Wiesbaden, Federal Republic of Germany

Blood flow velocities of the umbilical arteries were measured by Doppler ultrasonography during variable decelerations of the fetal heart rate. The flow velocity waveforms, being normal between uterine contractions, showed either an unchanged flow velocity waveform with an exclusive fetal heart rate effect on end-diastolic velocities or a rapid change to absent and reverse diastolic flow during the decelerations, indicating an abrupt increase in placental resistance with a halt in placental perfusion. Computer-aided reconstruction of the fetal heart rate curve revealed the exact temporal relationship between the reduction of umbilical artery perfusion and deceleration of fetal heart rate. We showed that variable decelerations of fetal heart rate can be observed during only slightly changed umbilical perfusion or can be caused by a halt in placental perfusion, which does not necessarily mean an absence of any movement of the fetal blood column, but is a result of a systolic forward and diastolic reverse flow to the same extent. (Am J Obstet Gynecol 1991;164:534-40.)

Key words: Doppler ultrasonography, variable decelerations, umbilical cord occlusion

Doppler ultrasonographic examinations of fetal and maternal vessels are of increasing importance in the antenatal diagnosis of fetal well being and in the diagnosis of placental insufficiency.[1-5] Changes in umbilical artery waveforms can be explained by the fact that changes in placental downstream resistance are caused by histomorphologic alterations of the fetal placenta.[6,7,8] Thus alterations of the umbilical artery waveform without uterine contractions describe a chronic state of the placenta rather than acute parameters of the fetal condition. However, it is interesting that the far more acute changes of flow patterns that might occur in labor have been examined so far by only a few authors. During normal labor the blood flow curves of the fetal aorta descendens[9] are unchanged. The umbilical artery flow velocity waveform shows no significant changes in the systolic/end-diastolic (S/D) ratio throughout normal labor as well.[10,11] We could find only a few publications on Doppler flow measurements of the umbilical artery during typical variable decelerations of the fetal heart rate (FHR) in human beings.[12,13] We thought such an examination allowed an interesting insight into the mechanisms of FHR alterations, which are thought to be caused by flow changes during umbilical cord compression.[14,15]

Patients and methods

Eight gravid women were examined during the first stage of labor. In all cases the membranes had ruptured spontaneously or an amniotomy had been performed. The cervix was dilated from 2 to 7 cm. All patients had epidural induction of anesthesia. In all patients regular contractions were present, and cardiotocographic monitoring was carried out continuously by means of an external tocotransducer and a fetal scalp electrode (Hewlett Packard model 8040, HP, Boeblingen, Federal Republic of Germany).

Doppler signals from the umbilical arteries were recorded with a pulsed-wave Doppler system with a 3 MHz duplex transducer (UltraMark 4, Advanced Technological Laboratories, Bothell, Washington). During the examination the patients were in the left lateral decubitus position with head and chest slightly elevated. Fetal movement and fetal breathing were absent during the flow recordings. A 100 Hz thump filter was used routinely and the sample volume was positioned on one umbilical artery identified by real-time ultrasonography.

The technical problems of the flow measurements consisted of a lack of sufficient amniotic fluid and breathing movements of the pregnant woman's abdominal wall. This often led to a temporary loss of Doppler signal during the contractions. The Doppler signal was lost for >10 seconds in 45 of 130 measured contractions and in 50 instances the interruptions showed periods

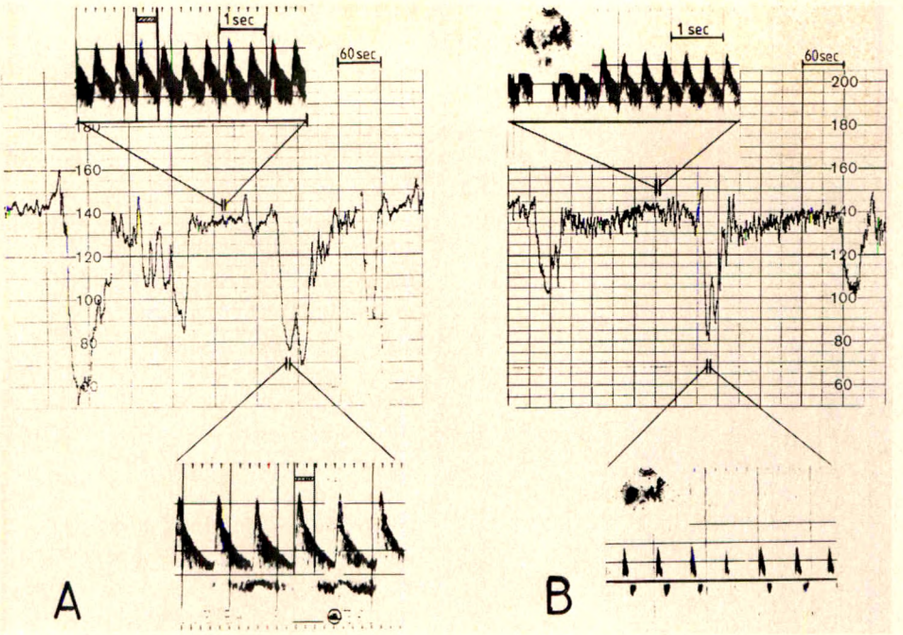

Fig. 1. Flow velocity waveform of umbilical artery before and during typical variable decelerations with FHR effect on flow velocity waveform **(A)** and reverse flow **(B)** during deceleration of FHR.

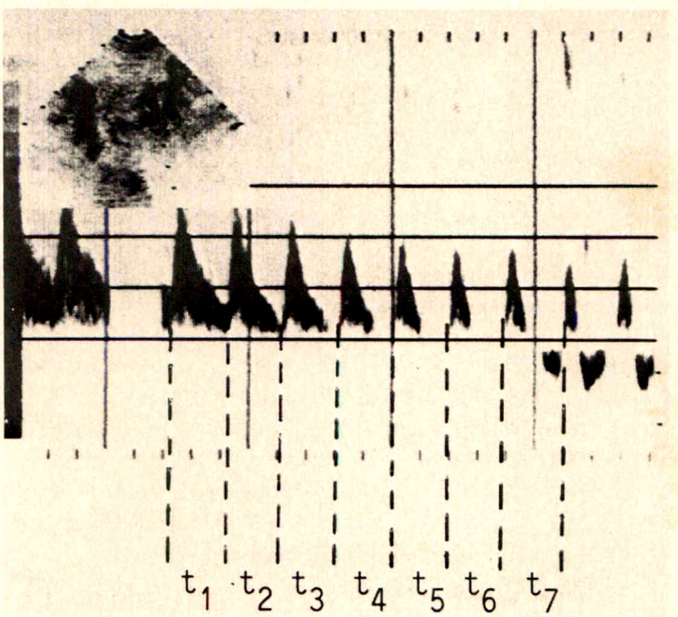

Fig. 2. Length of cardiac cycles on a flow recording during transition from normal flow velocity waveform to diastolic reverse flow = t_x.

of 5 to 10 seconds. Nevertheless acceptable recordings were achieved with a loss of the Doppler signal of <5 seconds during 35 contractions and we could register 22 of them as continuous recordings of the fetal umbilical blood flow during the complete duration of a deceleration. A minimum of two continuous recordings was possible for each fetus.

The flow measurements were continuously recorded

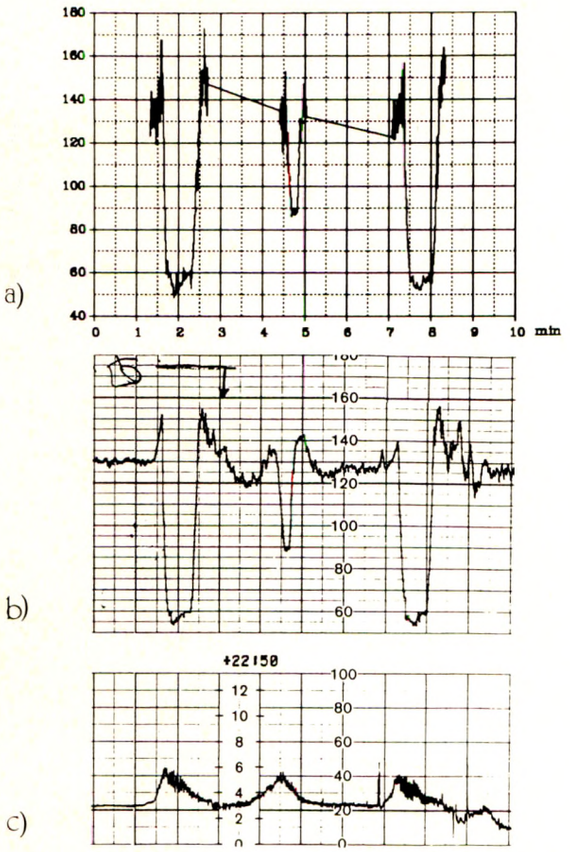

Fig. 3, a. Reconstruction of FHR curve by means of beat-to-beat measurement of Doppler flow velocity waveform; **b,** original FHR-tracing registered by means of scalp electrode; **c,** uterine activity by means of external tocotransducer.

on a video tape recorder. To analyze the flow velocity waveform, we used an IBM-AT personal computer and digitized the video images on a video frame grabber (PCVISION plus, Imaging Technology Inc., Woburn, Mass.). For measurements, a video analysis software was used (JAVA, Jandel Scientifics, Corte Madera, Calif.).

All patients gave informed consent to the study.

Results

Eight fetuses were examined by pulsed Doppler flow measurements of the umbilical arteries during the first stage of labor (39 to 41 weeks' gestation). Samples of fetal scalp blood showed normal pH values in all fetuses except one preacidotic value. Between contractions the blood flow curves showed S/D ratios between 2.0 and 2.5, which is in the normal range (10th to 90th percentile) of our own normal curve.

Although the FHR tracings showed typical variable decelerations in all cases, we recorded two completely different types of flow changes during uterine contractions with variable decelerations. Two fetuses showed a reduction of the diastolic flow velocities that can be exclusively attributed to an FHR effect (Fig. 1, *A*). The elongated heart cycle during the slowed down heart rate allows a decrease of end-diastolic frequency shifts to lower values. However, the pattern of the flow curves was not altered significantly and a measurement of diastolic velocities at a time interval that corresponds to an unchanged FHR reveals an unchanged S/D ratio. In contrast to this, the flow curves in the remaining six fetuses showed a rapid and marked reduction of S/D ratios and a diastolic reverse flow (Fig. 1, *B*). It is evident that an altered FHR is not responsible for the loss of end-diastolic velocities and, in particular, a diastolic reverse flow could not be explained by an extension of the diastolic length of the flow velocity waveform as a result of a decrease in FHR.

To analyze the exact temporal relationship between the decrease of the FHR during variable decelerations and the changes of the flow patterns, we measured the length of each cardiac cycle in the registered Doppler flow curves and calculated the beat-to-beat frequency for each cardiac cycle as it is shown in(Fig. 2). With commercial graphics software we could reconstruct the FHR curve. The result of such a reconstruction is shown in Fig. 3. The calculated FHR curve corresponds to the FHR tracing recorded by means of a scalp electrode.

The extension of the FHR curve to the paper feed velocity of the registered Doppler flow curves was now possible and thus an exact synchronization of FHR-curve and flow pattern was guaranteed.

In Fig. 4 the FHR is plotted simultaneously under the flow pattern, which shows a change to a diastolic reverse flow during a variable deceleration. It is obvious that the change to a diastolic reverse flow occurs 3 seconds before a slight acceleration and 9 seconds before the beginning of the deceleration of the FHR. A similar time delay could be seen in all examined fetuses and varied between a range of 4 to 10 seconds between the beginning of reverse flow and the beginning of the deceleration of the FHR. Furthermore, Fig. 4 shows that during the second part of the w-shaped deceleration, diastolic flow velocities were registered in the normal range again when the FHR was still below 100 beats/min.

To be able to estimate the extent of the flow reduction during the described changes in flow patterns, we measured the area under the flow curve in each cardiac cycle by use of the described video analysis system. The use of planimetry presumes that the flow velocities under the curve are distributed proportionally. In particular, during forward flow this leads to a slight underestimation of the flow inasmuch as there is a discontinuous distribution of the flow velocities with a higher density at the top margin of the curves. Nevertheless this is a sufficiently exact method to estimate the size

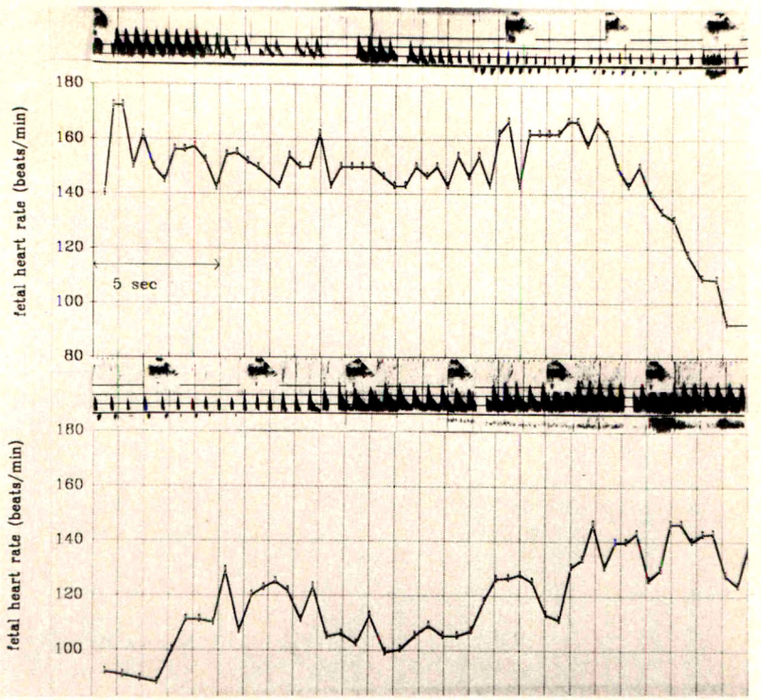

Fig. 4. Synchronized Doppler flow velocity waveform and reconstructed FHR tracing during variable deceleration with reverse flow.

of the flow. During deceleration of the FHR the length of each cardiac cycle is extended and therefore in cases of an unchanged flow velocity waveform the estimated flow per cardiac cycle increases. For that reason we calculated the flow per cardiac cycle and per minute. Setting the flow curve between the contractions in each case to 100%, we plotted the relative decrease in perfusion against the FHR. In Fig. 5 this is done for the deceleration shown in Fig. 4. There is a sharp decrease in umbilical perfusion before the FHR decreases. During the reverse flow the area under the curve in the forward flow channel is equal to that measured in the reverse flow channel and this corresponds to a movement of the blood column forward and backward to about the same extent. The umbilical perfusion reached normal values about 6 seconds before the FHR reached a normal baseline rate.

Fig. 6 shows the continuous registration of the Doppler signal in a case of an FHR-altered flow velocity waveform during a variable deceleration. The perfusion during this deceleration expressed as relative umbilical artery blood flow per minute is reduced simultaneously to the decelerating FHR (Fig. 7). However, whereas the FHR decelerates to about 50% of the normal baseline, the relative umbilical artery blood flow is reduced by only 30%. This is because of an increase of the area under the flow curve caused by the prolonged heart cycle and the unchanged flow velocity waveform during

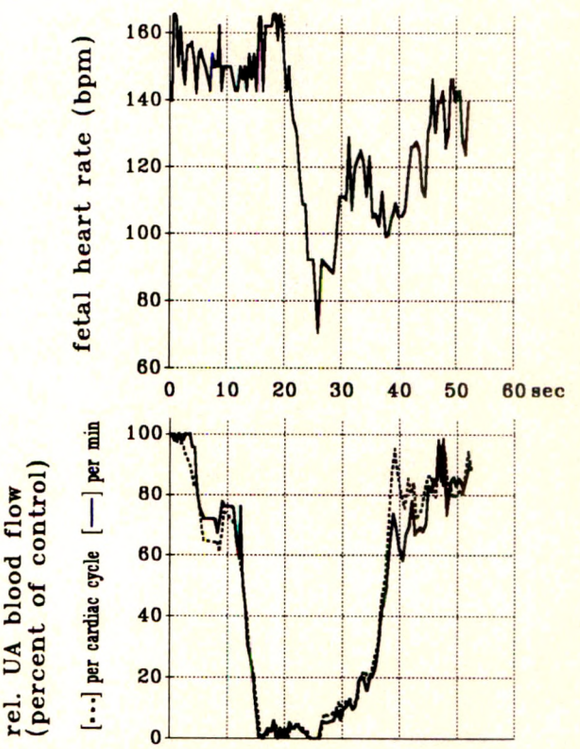

Fig. 5. Reconstructed FHR-tracing *(top)* and relative perfusion of umbilical artery during variable deceleration with reverse flow *(bottom)*.

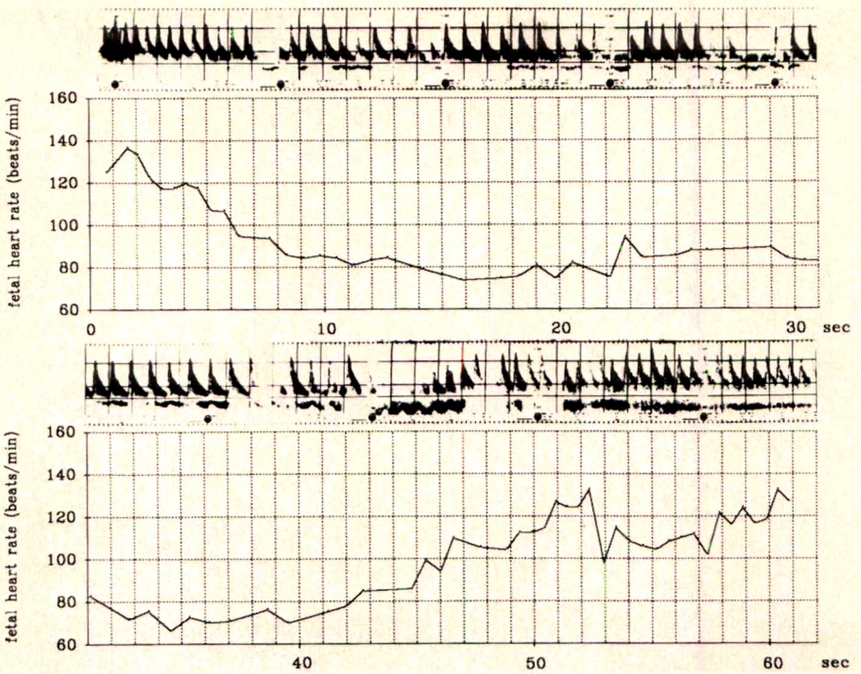

Fig. 6. Synchronized Doppler flow velocity waveform and reconstructed FHR tracing during variable deceleration with FHR effect on flow velocity waveform.

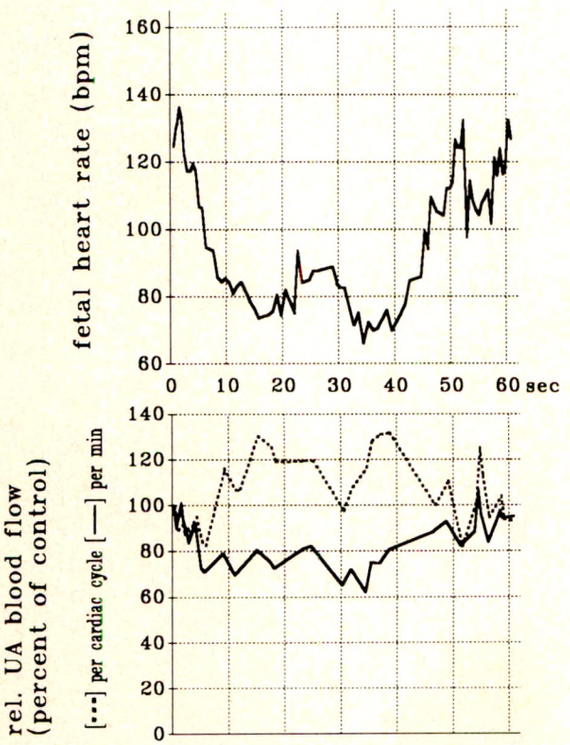

Fig. 7. Reconstructed FHR tracing *(top)* and relative perfusion of umbilical artery during variable deceleration with FHR effect on flow velocity waveform *(bottom)*.

the deceleration of the FHR. Therefore the calculated flow volume per heart cycle increases parallel to the decrease of the FHR, leading to only a slight reduction of perfusion per minute.

Comment

The effects of a reduction of the umbilical perfusion on fetal blood circulation were examined by several authors in sheep fetuses.[16, 17] Künzel et al.[17] could show that the reduction of umbilical vein perfusion by partial cord compression results in a marked increase of the umbilical vein blood pressure. Inasmuch as the systolic and diastolic blood pressure in the fetal aorta was only slightly elevated during umbilical vein occlusion, this led to a reduction of the perfusion pressure of the placenta. During systole the effective perfusion pressure was 75% and during diastole only 30% of control values. The direct evidence of the linear relationship between increase of umbilical vein pressure and decrease of the flow in the umbilical arteries was performed by Berman et al.[16] Furthermore, these authors showed the linear correlation between the mean arterial blood pressure and the blood flow in the umbilical arteries.

In our study we confirmed these experimental results also in the human fetus with the noninvasive Doppler method. In instances in which a significant reduction of umbilical perfusion is present, the recordings of the

flow profiles (in contrast with the overall measurements of blood flow with electromagnetic flow probes) allow an investigation of the mechanism of flow reduction in the umbilical arteries. We found that the reduction of perfusion is caused by a significant decrease of systolic velocities and by a halt in or reversal of flow of the blood column during diastole. Inasmuch as the perfusion pressure, that is the difference between aortic blood pressure and umbilical vein blood pressure, causes the forward flow through the placental vessels, we conclude that this arteriovenous pressure gradient decreased during the measured variable decelerations to diastolic values that were too low to cause forward flow through the placenta throughout the diastole. If the diastolic umbilical vein blood pressure is as high as the diastolic aortic blood pressure of the fetus, the diastolic venous outflow of the placenta decreases to zero. This situation is given in cases of a nearly total occlusion of the umbilical vein in which only the systolic arteriovenous pressure gradient is high enough to cause a venous outflow of the placenta. This status is present for some seconds during the transition from normal to reverse flow and vice versa (Fig. 4).

However, the total occlusion of the umbilical vein allows no venous passage, and therefore the stroke volume that is moved by the high systolic blood pressure in the fetal aorta into the arterial tree of the placenta, leads to a high diastolic pressure in the placental arteries, inasmuch as their compliance represents a second compression chamber. If its pressure exceeds the diastolic pressure in the aorta, a diastolic reverse flow from the arterial vascular tree of the placenta to the fetal aorta results.

This hypothesis induces that the complete occlusion of the fetal umbilical vein does not lead to a stop of the blood column in the umbilical arteries as could be assumed by the studies mentioned with electromagnetic flow measurement. On the contrary we found a highly pulsatile flow pattern in the umbilical arteries during cord compression. In our studies we showed that this causes a temporary ineffective perfusion by moving the blood column forward and backward to the same extent.

The continuous measurement of the umbilical artery flow velocity waveform by Doppler ultrasonography during variable decelerations of the FHR proves that two primary mechanisms exist that cannot be differentiated by analysis of the FHR tracings alone. The first one is discussed above and is in good agreement with the generally accepted opinion[14, 15] that variable decelerations are caused by a temporary mechanical occlusion of the umbilical perfusion. We showed that the decrease in effective flow in the umbilical artery to zero occurs at a time when the FHR does not yet show any alteration. The time interval between this initial event and the deceleration of FHR is in good agreement with the lag found in sheep after umbilical vein occlusion.[17] However, in some cases, variable decelerations of the FHR are obviously not caused by a mechanical reduction of the umbilical perfusion. Our results show that the only effect on umbilical perfusion in this case is a prolonged diastolic decrease of flow velocities as a result of the decelerated FHR. The reduction of the relative perfusion per minute is only moderate and is in sharp contrast to the marked deceleration of the FHR (Fig. 6). We conclude that this is a parasympathetic reaction of the central nervous system caused by a local or systemic hypoxemia of the fetus. Therefore Doppler examinations of the umbilical arteries during labor could help to differentiate whether decelerations of the FHR are caused by hypoxic reasons or by mechanical occlusion of the umbilical vein and subsequently by a halt in arterial perfusion. Further investigation is necessary to confirm the clinical value of our results.

A case report of giant cell arteritis of the uterus and adnexa

P.R. Summers, MD,[a] M.K. Biswas, MD,[a] D.W. Boulware, MD,[b] L. Green, MD,[c] E.H. Herrera, MD,[a] and A.G. O'Quinn, MD[c]

New Orleans, Louisiana

Giant cell arteritis of the uterus and adnexa is a rare disorder, which is generally asymptomatic and occasionally associated with temporal arteritis. The true clinical significance of this dramatic microscopic finding remains obscure, but arteritis of the uterus and adnexa may be associated with later development of giant cell arteritis elsewhere in the body. (Am J Obstet Gynecol 1991;164:540-2.)

Key words: Giant cell arteritis of uterus, pelvic vasculitis, temporal arteritis

The following case report concerns the appearance of giant cell arteritis in the uterus of a 68-year-old patient with temporal arteritis. Although giant cell arteritis of the uterus and adnexa is rare, doctors who are treating women with temporal arteritis should be alerted to the possibility for this associated condition, which may be asymptomatic.

Case report

A 68-year-old woman, gravida 1, para 0, abortus 1, was seen as an outpatient for routine gynecologic evaluation. Her only complaint was epigastric burning at night with mild episodic abdominal bloating; this was considered to be related to prednisone therapy for temporal arteritis, which was diagnosed 6 months earlier (Fig. 1). Palpation of an asymptomatic adnexal mass led to a pelvic ultrasonographic study that demonstrated a left ovarian cyst of 2.5 × 2.9 cm in size. At this point the patient refused surgery. A new finding of septation of the cyst was noted on repeat ultrasonographic evaluation 4 months later, although size of the cyst was unchanged. Total abdominal hysterectomy and bilateral salpingo-oophorectomy were performed. Pathologic evaluation of the surgical specimen demonstrated a serous cystadenoma of the left ovary with extensive granulomatous arteritis identified throughout the uterus, fallopian tubes, and ovaries (see Fig. 2). The patient's recovery from surgery was uneventful. Temporal arteritis was in remission, and she has not been treated with prednisone for several months now. She declined further steroid therapy for presumed persisting but asymptomatic pelvic arteritis.

Comment

Giant cell arteritis of the uterus and adnexa is indeed a rare finding. A review of the world literature reveals only 15 reported cases of this disorder that affects the uterus.[1] In two of these reported cases the patient was also noted to have temporal arteritis. The number of the remaining patients in whom symptomatic temporal arteritis eventually developed is not reported. No case of giant cell arteritis that involved other areas of the body could be found in the literature that is associated with this disorder of the uterus and adnexa. One would presume, though, that such an association with vascular disease in other organs would be likely, since giant cell arteritis is considered to be a disease with the potential for systemic involvement.[2]

One would assume that the severity of symptoms

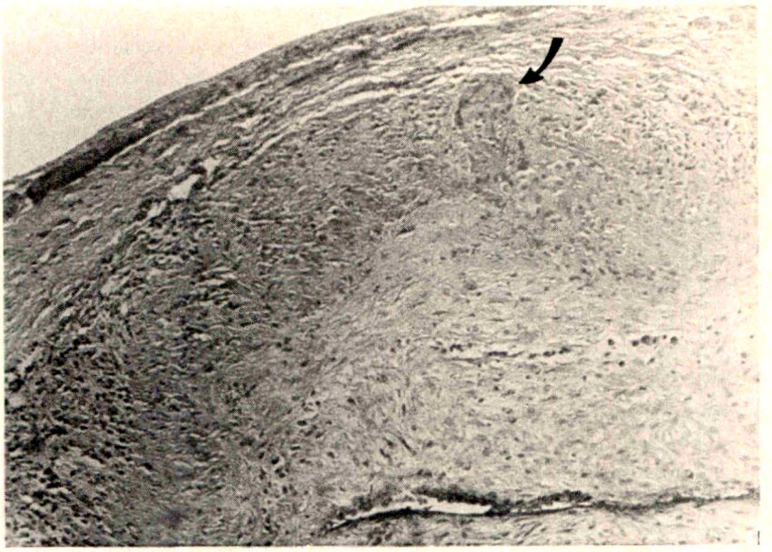

Fig. 1. Longitudinal section of temporal artery, that shows nodular thickening of vascular wall, slitlike appearance of vascular lumen, and near occlusion of the lumen. The tunica media is infiltrated by chronic inflammatory cells and histiocytes, with the formation of multinucleated giant cells *(arrow)*. (Hematoxylin-eosin stain; ×400.)

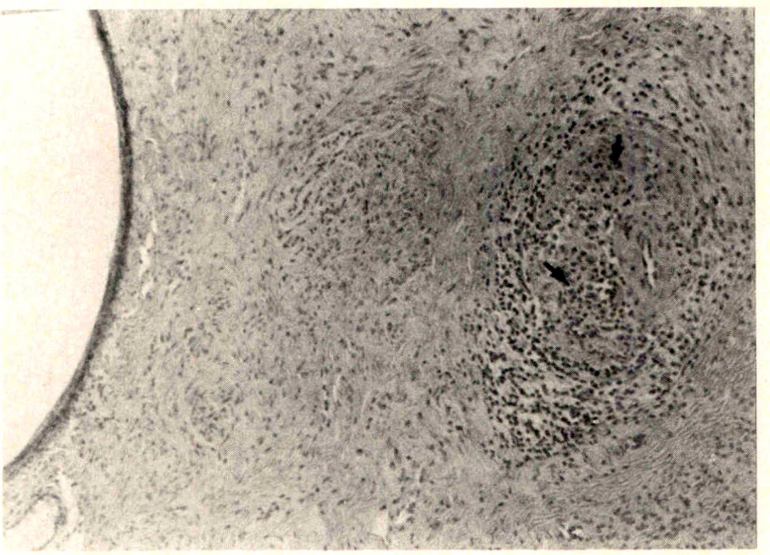

Fig. 2. Section of ovary. In this instance the inflammatory infiltrate within the vessel wall consists largely of chronic inflammatory cells; however, clusters of histiocytes are seen *(arrows)*. Note the markedly narrowed vascular lumen. (Hematoxylin-eosin stain; ×400.)

from giant cell arteritis would directly relate to the severity of organ involvement. A review of the literature review reveals no cases of symptomatic giant cell arteritis of the uterus. This is consistent with the asymptomatic status of the patient in this report. Her lack of symptoms may be related to the postmenopausal state with relative inactivity of the ovaries and endometrium. Yet it is surprising that this patient was totally free of symptoms, in view of the extensive vasculitis with multiple areas of arterial occlusion, which was seen microscopically throughout the surgical specimen.

Therapy for giant cell arteritis, a disorder of unclear

causes, is generally successful with a course of prednisone. It is surprising that this patient's previously symptomatic temporal arteritis remained clinically in remission during the episode of active pelvic vasculitis. One would presume that residual tissue in the pelvis after the patient's hysterectomy would continue to be involved with this inflammatory process, considering the extent of vasculitis in the surgical specimen. It is difficult to assess the significance of such residual disease after hysterectomy. This patient declined further steroid therapy for the detected pelvic vasculitis because of the unpleasant side effects she had previously experienced.

In summary, the true clinical significance of isolated giant cell arteritis of the uterus and adnexa in a postmenopausal patient remains obscure. In such a case, though, it would be logical to maintain surveillance for development of giant cell arteritis at other body sites. Careful physical examination and repeated evaluation of erythrocyte sedimentation rate would be important. Giant cell arteritis of the pelvis can occur, and physicians who are treating temporal arteritis should be aware of the possibility of association giant cell arteritis of the uterus and adnexa. It will be of interest if future similar case reports reveal associated menstrual disorders in premenopausal patients. Giant cell arteritis that is found coincidentally during evaluation of a hysterectomy specimen should warrant a search for temporal arteritis. Furthermore, the recommendation for treatment of asymptomatic giant cell arteritis of the pelvis is unclear, since this patient's untreated arteritis is thus far benign after more than 12 months of close follow-up.

Prospective analysis of sperm-oocyte fusion and reactive oxygen species generation as criteria for the diagnosis of infertility

R.J. Aitken, PhD,[a] D.S. Irvine, MD,[b] and F.C. Wu, MD[a]
Edinburgh, Scotland

We have undertaken a prospective analysis of the diagnostic significance of three different criteria of human sperm function including the conventional semen profile, measurements of hamster-oocyte fusion, and determinations of reactive oxygen species generation in 139 couples. The latter, who were characterized by a lack of detectable abnormalities in the female partner, were followed up for a maximum of 4 years to determine the incidence of spontaneous pregnancy in the absence of therapeutic intervention. Assessments of monthly fecundity with life table analysis techniques revealed a highly significant, positive relationship between fertility and hamster-oocyte fusion rates that were measured in the presence of the ionophore, A23187. Conversely, reactive oxygen species generation was shown to be negatively associated with both the outcome of the sperm-oocyte fusion assay and fertility in vivo. The clinical significance of these diagnostic techniques was emphasized by the fact that within the same data set, the conventional semen profile was of no significant diagnostic value. (Am J Obstet Gynecol 1991;164:542-51.)

Awareness of the deficiencies of the conventional semen profile as the sole means of the assessment of male fertility has led to the development of a new generation of alternative diagnostic tests that are based on a functional analysis of the fertilizing potential of human spermatozoa.[1] Foremost among these is a test intro-

duced by Yanagimachi et al. in 1976,[2] which is based on the unique ability of the zona-free hamster oocyte to fuse with human spermatozoa. The biologic significance of this fusion process is based on the fact that this event can only occur if the spermatozoa have undergone the acrosome reaction and successfully generated a fusogenic plasma membrane. Furthermore, the ultrastructural details of sperm-oocyte fusion in this system appear to be identical to the homologous situation in that fusion with the oolemma is initiated by a discrete area of plasma membrane that overlies the equatorial segment of acrosome-reacted spermatozoa.[3]

As a means of diagnosing male fertility the general consensus of the retrospective studies that addressed this issue is that this procedure has the potential to discriminate between fertile and infertile men, although in practice there has been a general failure to standardize the methods for the test and to introduce appropriate quality control measures.[4, 5] The only two prospective studies[6, 7] that have investigated the long-term prognostic value of the test have tended to confirm the ability of the zona-free hamster-oocyte penetration test to indicate the relative fertility of male patients, although some resultant pregnancies were recorded for subjects who exhibited abnormal penetration test results.

In evaluation of this particular test it must be recognized that: (1) the zona-free hamster oocyte penetration assay is only capable of generating information on one component of sperm function, namely the ability of acrosome-reacted cells to initiate sperm-oocyte fusion and (2) the major biologic defect of the assay is that it is entirely dependent on the occurrence of spontaneous acrosome reactions in populations of human spermatozoa that have been incubated in vitro. This is unsatisfactory because the incidence of spontaneous acrosome reactions in vitro is extremely low (5% to 10%),[8] and the mechanisms by which this event is triggered by prolonged incubation may bear no relationship to the physiologic process as it occurs in vivo.

To address this inherent defect in the sperm penetration assay we modified the protocol for this test[9] by including the divalent cation ionophore, A23187, in the preincubation medium. The purpose of the ionophore is to generate those intracellular changes in pH and free ionic calcium that are responsible for initiation of the acrosome reaction,[10] and to this extent, the action of A23187 is physiologic. Under the influence of this reagent, an increase in the proportion of acrosome-reacted cells manifests itself as a highly significant rise in the levels of sperm-oocyte fusion, at least within the normal fertile population.[9] However, in certain cases of male infertility the intracellular signals that are generated by A23187 are not sufficient to stimulate an enhancement in the levels of sperm-oocyte fusion.[9] Such refractoriness to ionophore stimulation suggests that in these patients there are defects in the spermatozoa, downstream from calcium influx, that prevent the plasma membrane from undergoing those fusogenic changes that are normally associated with the acrosome reaction and penetration of the oocyte. Recent studies in this area have suggested that pathologic events, that involve the peroxidation of unsaturated fatty acids in the sperm plasma membrane may be responsible for this refractory state.[11, 12] This peroxidative damage appears to be initiated by the excessive generation of reactive oxygen species by the ejaculate and results in a loss of membrane fluidity and integrity such that the spermatozoa are no longer able to exhibit biologic responses in the presence of ionophore.[11-13]

In view of these results, we undertook a detailed evaluation of reactive oxygen species generation and A23187-induced sperm-oocyte fusion in the diagnosis of human infertility. This evaluation took the form of a prospective study in which the incidence of spontaneous pregnancy was monitored during a median follow-up period of 510 days in 139 untreated couples who were characterized by a normal female partner. We believe that this is a unique data set that sheds new light on the diagnostic potential of these tests.

Patients and methods

Patients. This study was based on a prospective analysis of the incidence of spontaneous pregnancy in 139 couples who were characterized by a normal female partner, in terms of history and examination, menstrual cycle duration and regularity, and the outcome of a diagnostic laparoscopy including a tubal patency test that is based on the passage of methylene blue through the female reproductive tract. The male partners were unselected, apart from the exclusion of azoospermia, and a full description of their semen profiles is given in the Results section. The median duration of infertility at the time of analysis was 60 months with 10th to 90th percentiles of 36 and 120 months.

Study design. A detailed semen analysis was performed for each male partner including the conventional profile, zona-free hamster oocyte penetration test, and assessment of reactive oxygen species generation. The couples were then left untreated for a median follow-up period of 17 months, with 10th to 90th percentiles of 8.3 to 33.3 months, during which time 32 women (23%) spontaneously conceived. An analysis of the relationship between the criteria of semen quality that was measured at the beginning of the study and the subsequent incidence of spontaneous pregnancy was then performed. In this way, a measure of the relative prognostic value of the hamster oocyte penetration test, reactive oxygen species generation, and conventional semen profile was obtained.

Statistics. In view of the abnormal distribution that was exhibited by a majority of the variables, the data are presented as median values with 10th to 90th percentiles, and parameteric forms of analysis such as multivariate discriminant analysis have been avoided. Differences in the distribution of data between groups were assessed with the Mann-Whitney U test, and differences in frequency were evaluated by χ^2 analysis. Where linear regression coefficients have been calculated the data have been transformed ($\sqrt{x}$, log x, log 1 + x) to optimize the normality of the data distribution.

Life table analysis was performed with the procedures described by Cramer et al.,[14] which generated data on the cumulative pregnancy rate and monthly fecundity.

Conventional semen profile. The patients produced semen samples for analysis by masturbation into sterile plastic containers. After at least 30 minutes was allowed for liquefication to occur, a semen profile was constructed with the procedures described by the World Health Organization[15] and included measurement of sperm concentration, total count, percent normal morphology, and percent motility.

Hamster oocyte penetration test. The spermatozoa were washed by repeated cycles of dilution and centrifugation (500 g for 5 minutes) with 5 to 8 ml volumes of medium BWW[16] and finally resuspended at a concentration of 20×10^6 cells/ml. They were then diluted with an equal volume of BWW that contained an aqueous suspension of the calcium magnesium salt of A23187 as described previously.[9] All samples were subjected to a 3-hour exposure to A23187 at a final concentration of 0.025 mg/ml, which we previously showed to be optimal for a majority of specimens.[9] In 33 cases, however, sufficient material was available to carry out an additional assessment of sperm-oocyte fusion at a dose of 0.05 mg/ml. In such cases in which the spermatozoa were examined at two doses of ionophore, the higher result was taken for analysis. After this 3-hour incubation with ionophore, the samples were formed into pellets by centrifugation (500 g for 5 minutes) and resuspended at a concentration of 10×10^6/ml before dispersal as 50 μl droplets under liquid paraffin. Zona-free hamster oocytes were then introduced into the droplets (approximately 20 oocytes per sample) and after a further 3 hours of incubation, they were examined for the presence of decondensing sperm heads by phase-contrast microscopy at a magnification of ×250.

In every test run a quality control sample of known fertilizing capacity was monitored to confirm the validity of the assay in terms of medium composition of oocyte integrity. These control samples gave a mean penetration rate of 74.0% ± 2.9% with an average of 3.0 ± 0.3 spermatozoa fusing with each oocyte (n = 70).

Reactive oxygen species generation. Reactive oxygen species generation was monitored with the chemiluminescent techniques described previously, and luminol (5-amino-2,3-dihydro-1,4 phalazinedione) was used as the probe. In brief, suspensions of human spermatozoa at 20×10^6 cells/ml in a volume of 500 μl were exposed to 1 μl of luminol that was stored as a 100 mmol/L stock solution in dimethyl sulfoxide. Five hundred microliters of either medium BWW (control) or medium BWW that contained A23187 (0.05 mg/ml aqueous suspension of the calcium magnesium salt) was then added, and the chemiluminescence was monitored as counts integrated over a 10-second period after an incubation period of 3 minutes in a Berthold Biolumat, L139500T luminometer (Berthold Analytical Instruments Inc., Nashua, N.H.).

Results

Analysis of the conventional parameters of semen quality for this patient population gave median (10th to 90th percentile) values for sperm concentration and motility and normal morphology of 56 (16.0 to 156.2) $\times 10^6$ cells/ml, 53% (12% to 65%) and 46.5% (21.7% to 64.6%), respectively. Of the 139 patients who were examined in this study, a majority (75) were normospermic according to the criteria that we established for our local fertile population of $>20 \times 10^6$ spermatozoa per milliliter, >40% normal morphology, and >40% motility.[17] Of the remainder, 23 were normal except for isolated mild teratospermia (30% to 40% normal morphology), and in 10 other patients the isolated teratospermia was more severe (<30% normal). Six patients exhibited isolated asthenospermia, and in eight patients motility and morphology were defective (asthenospermia and teratospermia), but the sperm count was normal. In two patients isolated oligospermia was seen and in another two, the oligospermia was associated with asthenospermia. In four patients the low sperm counts were associated with teratospermia and in nine, the complete oligoasthenoteratospermia syndrome was observed.

Reactive oxygen species. The chemiluminescent technique that was used to monitor reactive oxygen species production revealed an extremely wide range of spontaneous activity on the part of the washed sperm preparations. The median basal chemiluminescent signal was 237 counts per 10 seconds and the 10th and 90th percentiles were 88 and 10,034 counts per 10 seconds, respectively. After the addition of ionophore A23187 there was a significant elevation of reactive oxygen species production ($p < 0.001$) to give a median value of 815 counts per 10 seconds and 10th and 90th percentile figures of 144 and 34,056 counts per 10 sec-

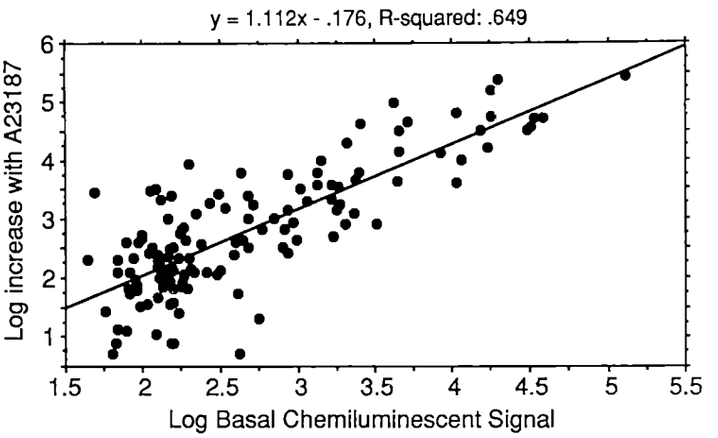

Fig. 1. Relationship between basal, spontaneous level of reactive oxygen species generation and degree of enhancement observed in presence of A23187.

onds. The magnitude of response to A23187 again showed considerable variation from individual to individual; the median difference between the basal-stimulated and A23187-stimulated signals was 341 counts per 10 seconds, and the 10th and 90th percentile values were 9 and 25,942 counts per 10 seconds, respectively. Linear regression analysis following logarithmic transformation of the chemiluminescent data revealed that the magnitude of the cellular response to A23187 was highly correlated ($r = 0.805$; $p < 0.001$) with the basal, spontaneous level of reactive oxygen species generation (Fig. 1).

Zona-free hamster oocyte penetration. In 136 patients the spermatozoa were assessed with the zona-free hamster oocyte penetration test after the induction of the acrosome reaction with A23187. This population of patients exhibited a wide range of functional competence according to this test, which provided a median percentage penetration value of 26.7% (10th to 90th percentiles of 0% and 100%, respectively); corresponding figures for the mean number of spermatozoa that fused with each oocyte were 0.278 and 0 to 4.206.

Relationship between sperm-oocyte fusion and reactive oxygen species generation. Scatterplot analysis of the relationship between reactive oxygen species generation and sperm-oocyte fusion revealed the same negative association between defective sperm function and high basal levels of reactive oxygen species production that we observed in earlier studies (Fig. 2). If, on the basis of published analyses of the normal fertile population,[13] we took the thresholds of normality to be 10,000 counts per 10 seconds before the addition of A23187 and 30,000 counts per 10 seconds at 3 minutes after the addition of ionophore, then seven patients were found to exhibit abnormally high levels of reactive oxygen species generation. Within this subpopulation

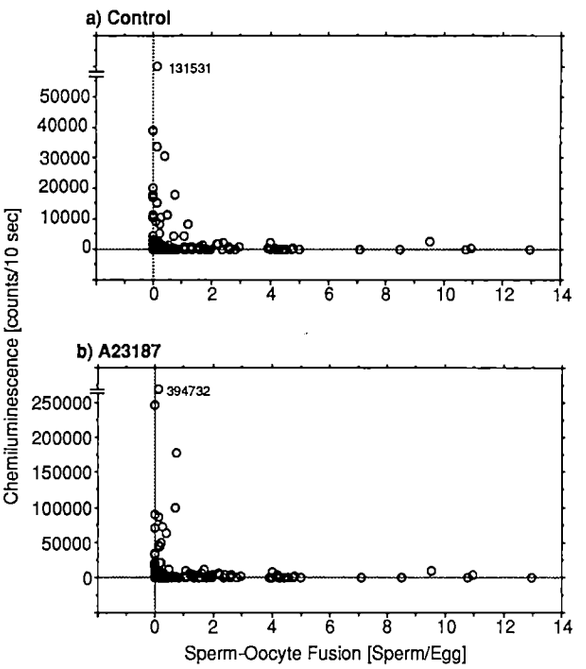

Fig. 2. Scatterplots of relationship between sperm-oocyte fusion and **(a)** control and **(b)** A23187-stimulated levels of reactive oxygen species generation.

of patients the spermatozoa exhibited a median (10th to 90th percentile) of only 10% (0% to 45.6%) oocyte penetration and 0.1 (0 to 0.6) sperm fusions per oocyte. This level of sperm-oocyte fusion was significantly ($p = 0.0026$) lower than that in the remainder of the study population.

Relationships with pregnancy

Luminol signal. Analysis of the relationship between reactive oxygen species generation and spontaneous pregnancy rate revealed a clear negative association as

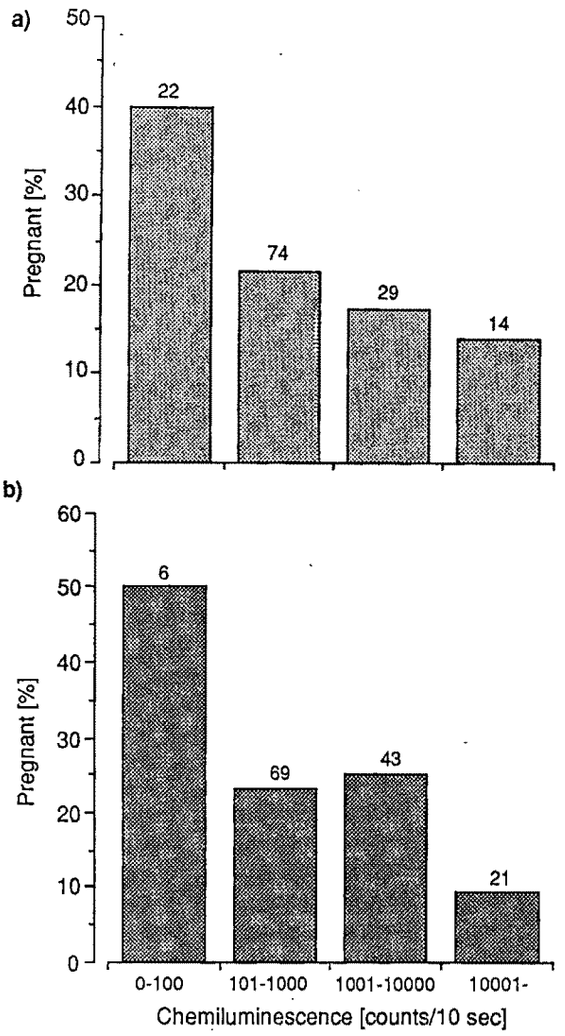

Fig. 3. Incidence of spontaneous pregnancy in relation to levels of reactive oxygen species generation observed in **(a)** absence and **(b)** presence of ionophore, A23187.

illustrated in Fig. 3. Analysis of the basal chemiluminescent signal, which was obtained in the absence of A23187 (Fig. 3, *a*), revealed the presence of a cohort of highly fertile patients ($n = 22$) who exhibited very low levels of reactive oxygen species production (chemiluminescent counts <100 counts per 10 seconds) in association with a high pregnancy rate of 40%. When the basal chemiluminescent counts increased to between 101 and 10,000 counts per 10 seconds, the pregnancy rate was halved to around 20%, and with basal luminol signals of >10,000 counts, a pregnancy rate of 14% was recorded.

After the addition of A23187 the chemiluminescent signals were significantly elevated ($p < 0.001$). However, six patients still exhibited luminol counts of <100 counts per 10 sec, and three (50%) of them spontaneously achieved pregnancy. With chemiluminescent counts of 100 to 10,000 the pregnancy rate remained at around 20%, and with counts above 10,000 only 9% (2 of 21) of the patients initiated a pregnancy; none of the four male patients who exhibited luminol signals of >100,000 counts per 10 seconds was successful in this regard (Fig. 3, *b*).

Table I. Monthly fecundity rates for different levels of spontaneous reactive oxygen species generation

Chemiluminescent (counts/10 sec)	*No. of patients*	*Monthly fecundity*	*95% Confidence intervals**
0-100	22	0.012	0.0042-0.02
101-1000	74	0.0057	0.0029-0.0084
1001-10,000	29	0.0045	0.0006-0.0085
>10,000	14	0.0033	0-0.0084

*Two-sided.

Life table analysis of cumulative pregnancy rates against basal levels of reactive oxygen species production gave monthly fecundity values that ranged from 0.012 to 0.0033 for patients at the extremes of the data distribution (Table I). Comparison of the monthly fecundity values for each stratum of the reactive oxygen species data set, with the Z statistic described by Cramer et al.,[14] revealed significant differences ($p < 0.05$) in the monthly fecundity rates between the group that exhibited the lowest chemiluminescent count of 0 to 100 counts per 10 seconds and the monthly fecundity values that were recorded for all the other levels of reactive oxygen species generation (Fig. 4, *a*).

Life table analysis also indicated a decline in monthly fecundity values with increasing levels of reactive oxygen species generation in response to A23187 (Fig. 4, *b;* Table II). The particularly low monthly fecundity value that was obtained for patients who exhibited high chemiluminescence responses (more than 10,000 counts per 10 seconds) after stimulation with A23187 (monthly fecundity = 0.0023) was significantly lower than the monthly fecundity values that were recorded for the patients who exhibited reactive oxygen species generation in the ranges of 0 to 100 and 101 to 1000 counts per 10 seconds. Conversely, the relatively high monthly fecundity value (0.016) that was recorded for the small group of patients who exhibited the lowest (less than 100 counts per 10 seconds) level of reactive oxygen species generation was significantly ($p < 0.05$) greater than the monthly fecundity values that were recorded for all the higher levels of activity.

Thus the most telling components of the reactive oxygen species data set appeared to be at the extremes of the frequency distribution rather than at the center, where the median values (10th to 90th percentile) for the pregnant and nonpregnant cohorts of patients were

not significantly different at 181 (75 to 4645) and 271 (941 to 10,700) counts per 10 seconds in the absence of A23107 and 518 (116 to 9301) and 875 (157 to 42,010) in the presence of this reagent.

Hamster oocyte fusion. An analysis of the incidence of pregnancy against hamster oocyte penetration rate is presented in Fig. 5. The results reveal the existence of a clear positive relationship between this criterion of sperm function and fertility, regardless of whether sperm per oocyte or percentage penetration is used as the end point for the assay. A false-negative pregnancy rate of 4.1% (1 of 24) was recorded for the patients who exhibited 0% penetration in the hamster oocyte assay. Thereafter the pregnancy rate increased with the level of oocyte penetration reaching a maximum of 46% (17 of 35) in patients who exhibited an oocyte fusion rate of 75% to 100% or 44% (19 of 47) pregnant for those who exhibited a degree of polyspermy of more than one penetrating sperm per oocyte.

This relationship between the frequency distribution of the hamster oocyte penetration data and fertility was also reflected in significant differences between the pregnant and nonpregnant populations in terms of the overall distribution of the data (Mann-Whitney U test, $p = 0.0001$). The fertile population was characterized by a median (10th to 90th percentile) penetration rate of 78.9% (13.4% to 100%) with an average of 1.87 (0.13 to 4.88) spermatozoa penetrating each oocyte, and the nonpregnant group exhibited median values of 18.7% (0% to 93.7%) penetration and 0.2 (0 to 2.8) sperm per oocyte, respectively.

Life table analysis also confirmed the significant difference in cumulative pregnancy rates for men who exhibited different levels of hamster oocyte fusion. For the purpose of this analysis, an arbitrary threshold of 10% oocyte fusion was used to divide the patient population into two fractions according to the precedent set by Corson et al.[6] This analysis revealed significantly different ($p < 0.001$) monthly fecundity values of 0.0017 for the patients who exhibited less than 10% sperm oocyte fusion and 0.0081 for cases in which more than 11% of the oocytes were penetrated (Fig. 6).

Analysis of the conventional semen profiles for these

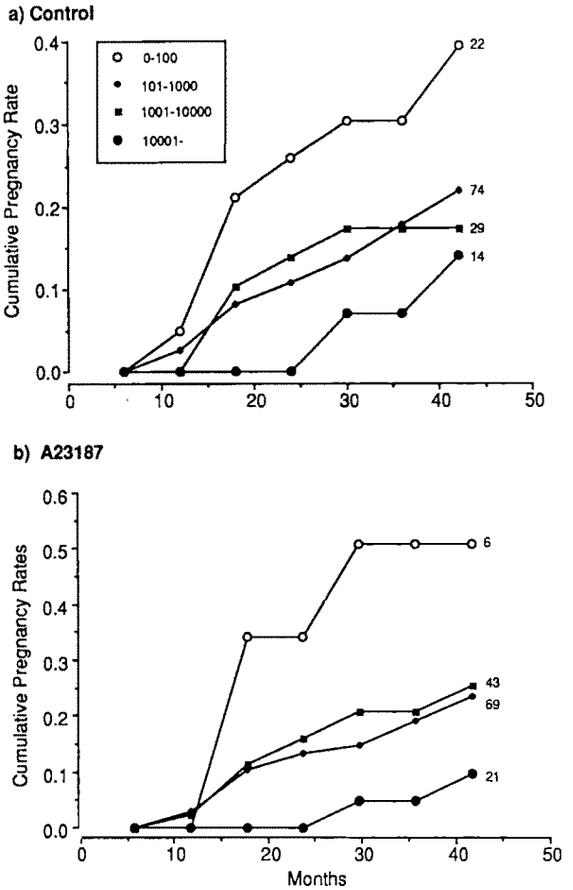

Fig. 4. Cumulative pregnancy rates for patients who exhibited different levels of reactive oxygen species generation in **(a)** absence and **(b)** presence of ionophore, A23187.

two groups of patients revealed significant differences ($p < 0.001$) in the central tendencies for all criteria (sperm concentration, total count, motility, morphology) that were assessed, although considerable overlap was observed at the extremes of the frequency distributions. Hence, although the median (10th to 90th percentile) values for sperm concentration, motility, and morphology for the patients who exhibited <10% hamster oocyte fusion were 33 (6 to 84) $\times$ 10^6 cells/ml, 47 (25% to 62%) and 39 (24% to 58%), respectively, the equivalent values for patients who exhibited more than 11% oocyte fusion were 69 (27 to 165) $\times$ 10^6 cells/ml, 55% (37% to 66%), and 56% (33% to 69%).

Conventional semen profile. There was no significant difference in the distribution of motility data between the pregnant and nonpregnant groups (Mann-Whitney U test), and the incidence of pregnancy was not significantly different (χ^2 analysis) between the patients who exhibited asthenospermia (<40% motility) (5 of 26; 19%) and the remainder of the study population (27 of 113; 24%).

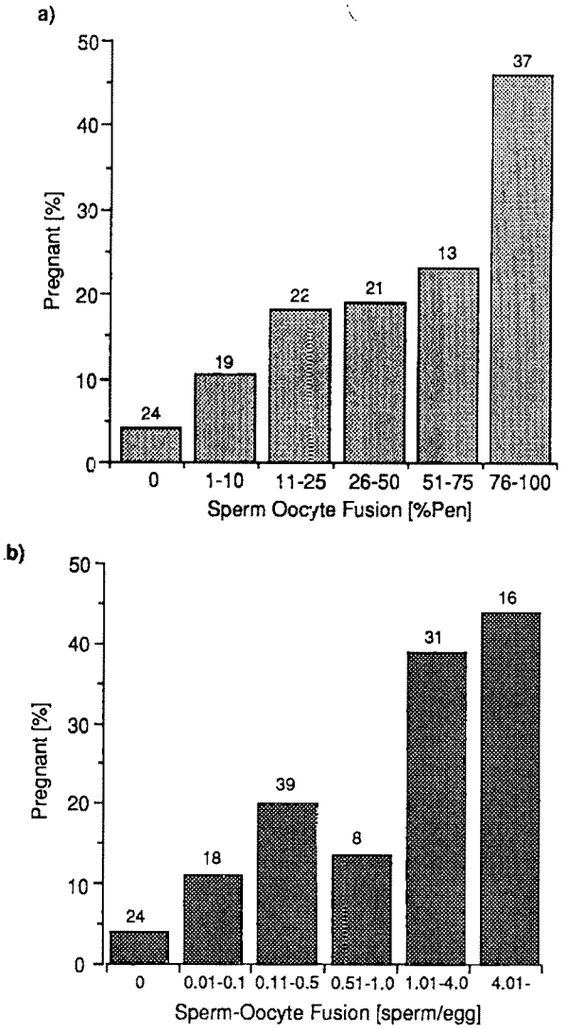

Fig. 5. Incidence of spontaneous pregnancy in relation to levels of sperm-oocyte fusion in hamster-oocyte penetration test expressed as **(a)** percentage of oocytes penetrated and **(b)** mean number of fusions per oocyte. *% Pen,* Percentage penetrated.

In contrast, there was a significant difference in the percentage of cells that exhibited a normal morphology in the pregnant and nonpregnant populations ($p = 0.01$; Mann-Whitney U test). However, if the conventional threshold of normality of (>40%) normal morphology was applied to these data, then the incidence of pregnancy was found to be no different (χ^2 analysis) in the teratospermic (<40% normal morphology) population (9 of 47; 19.1%) than in the remainder of the study population (20 of 69; 28.9%). Furthermore, life table analysis gave similar monthly fecundity values for patients who exhibited teratospermia (monthly fecundity = 0.0047) compared with the remaining population (monthly fecundity = 0.0071; Fig. 7, *a*).

Similar data were obtained for the relationship between sperm concentration and fertility. Hence, although the overall distribution of sperm concentration values in the pregnant and nonpregnant populations was significantly different (Mann Whitney U test; $p = 0.01$) the incidence of pregnancy in the patients who exhibited oligospermia (<20 × 10^6 cells/ml) (3 of 17; 17.6%) was not significantly different (χ^2 analysis) from the remainder of the study population (26 of 122; 21.3%). Furthermore, the monthly fecundity value for the patients who exhibited oligospermia (monthly fecundity = 0.0047) was not significantly different from that of the rest of the study population (monthly fecundity = 0.0063; Fig. 7, *b*).

Comment

This study has generated unique information on the prognostic value of conventional, biochemical, and functional techniques for the diagnosis of male fertility. The power of this analysis lies in the prospective design of the study in which confounding factors such as empirical treatments and variations in the fertility of the female partners have, as far as possible, been ruled out. We know of no other studies in which these criteria for the evaluation of diagnostic techniques in the male patient have been met, despite the fact that such prospective studies represent the most powerful (and perhaps the only truly valid) means of assessment of the clinical utility of such tests.

Apart from the normality of the female partner, the only other selection criterion that was used in this study was that the male partner should not be azoospermic. As a consequence of this selection policy, the study population presented with a wide range of seminal phenotypes, including patients who would have been classified as abnormal according to the conventional criteria of semen quality by virtue of deficiencies in the number, motility, or morphology of the spermatozoa. Life table analysis indicated that patients who were classified as abnormal under these circumstances were no less fertile than the remainder of the study population, which emphasizes, once again, the limited diagnostic value of the conventional semen profile.

In contrast, the zona-free hamster oocyte penetration test was shown to be of significant prognostic value in this prospective study. This particular test has been criticized repeatedly since its introduction because of a lack of standardization and poor quality control.[4] Standardization of the methodology is an issue that the World Health Organization has attempted to address by publishing a concensus protocol that was produced by consultation with experts in this particular field.[5] Despite the value of such a standardized protocol for the routine laboratory practice of the hamster oocyte penetration test, its biologic basis resides in the extremely low incidence of spontaneous acrosome reac-

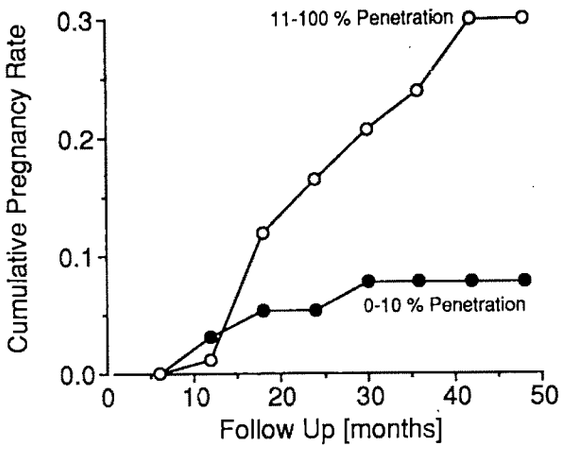

Fig. 6. Cumulative pregnancy rates for patients who exhibited sperm-oocyte fusion rates of more or less than 10%.

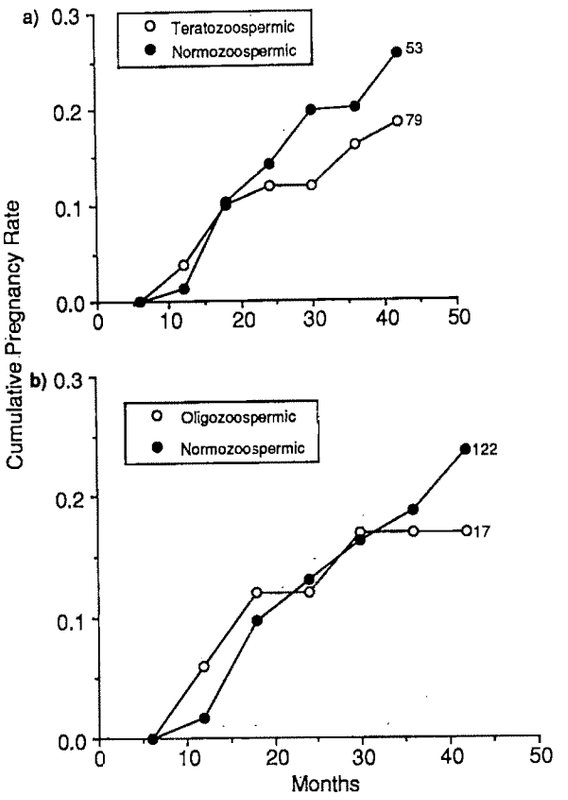

Fig. 7. Cumulative pregnancy rates for patients who exhibited **(a)** levels of normal sperm morphology of more or less than 40% and **(b)** sperm concentration of more or less than 20×10^6 cells/ml.

tions that occur in populations of human spermatozoa that are incubated for prolonged periods of time in vitro. We have therefore introduced a variation of this test procedure in which acrosome reactions are artificially induced by the ionophore A23187, which stimulates a simultaneous calcium influx into and a proton efflux from these cells. In response to this reagent, significantly enhanced levels of sperm-oocyte fusion are observed with sperm suspensions that have been obtained from normal fertile donors. In contrast, spermatozoa from male patients who exhibited overt evidence of infertility (e.g., oligospermia) produce low levels of sperm-oocyte fusion in the presence of A23187, which indicates that there are defects in these spermatozoa downstream from second messenger generation.[9]

The A23187-enhanced zona-free hamster oocyte penetration test should therefore be regarded as a variant of the basic assay that specifically generates information of the ability of human spermatozoa to respond to the calcium and pH signals that are generated by the ionophore with sperm-oocyte fusion. Because changes in intracellular calcium and pH seem to be the physiologic signals that activate mammalian spermatozoa in the presence of the zona pellucida, this version of the assay is not without a sound biologic foundation.[10, 18]

In previous studies we showed that the A23187-enhanced hamster oocyte penetration test gives an accurate indication of relative fertility in the settings of both artificial insemination by donor[19] and in vitro fertilization.[20] In the present investigation we confirmed the diagnostic value of this version of the test in a prospective study that focused on the incidence of spontaneous pregnancy. The results indicate the existence of a clear positive relationship between the levels of hamster-oocyte fusion and fertility with a low incidence (4%) of false-negative results, that is, patients who exhibit 0% sperm-oocyte fusion who achieve pregnancy.

This low incidence of false-negative results is extremely important because it is the 0% scores that, in principle, bear heavily on patient management. The validity of such scores depends critically on the quality of the assay and the nature of the protocol. In terms of quality, it is imperative that appropriate quality control measures be taken, including the inclusion of positive, fertile samples with every assay. In terms of protocol, the addition of A23187 appears to increase the sensitivity and predictability of the assay as judged from the low incidence of false-negative results and the improved segregation of patients who exhibited high and low fertility. Hence, although Corson et al. observed a twofold difference in the monthly fecundity rates between patients who exhibited penetration rates of more or less than 10% in an assay that lacked ionophore, we observed a fivefold difference in monthly fecundity rates between patients who exhibited such scores in the presence of A23187.

The major problem with the hamster oocyte test is

that it is a complex bioassay that only dedicated gamete biology laboratories can perform with precision. The principal role of this test should perhaps be as a bioassay of human sperm function in fundamental studies that are designed to elucidate the biochemical basis of defective sperm function. Once this objective has been achieved, the bioassay may be replaced by biochemical criteria that are more suited to routine diagnostic application.

Impaired fusion with zona-free hamster oocytes may involve multiple causes, and so it is doubtful whether the information that is generated by this complex bioassay could ever be substituted by a single chemical assessment. However, our recent studies identified at least one cause of poor sperm-oocyte fusion that might constitute the first of a battery of biochemical tests for the assessment of human sperm function. In these cases, the causative mechanism involves the induction of peroxidative damage to the unsaturated fatty acids that predominate in the sperm plasma membrane as a result of exposure to high levels of hydrogen peroxide and oxygen free radicals.[11-13, 21] In this study we examined the oxidative stress to which spermatozoa are subjected with the use of a simple chemiluminescent assay for reactive oxygen species, which is based on the oxidation of luminol.[11] The results generated with this technique exhibited a negative correlation with sperm-oocyte fusion rates, as observed in previous studies.[11-13] Furthermore, a negative correlation was also observed between the levels of reactive oxygen species generation and the incidence of spontaneous pregnancy in vivo. The chemiluminescent signals that were generated by the washed sperm preparations were particularly informative at the extreme ends of the frequency distribution. Samples that exhibited basal chemiluminescent signals of <100 counts per 10 seconds were three to four times more likely to achieve a pregnancy than those that exhibited signals >10,000 counts per 10 seconds. If the chemiluminescent signal remained <100 counts per 10 seconds after addition of A23187, the patients' monthly fecundity value was about seven times higher (monthly fecundity values of 0.016 compared with 0.0023) than that of those patients who exhibited counts >10,000 per 10 seconds after ionophore treatment. The measurement of reactive oxygen species generation by the washed ejaculates therefore provides data of prognostic value, albeit for the subsets of patients who exhibited extremely high or low levels of activity.

Nevertheless, it must be emphasized that the observed relationship between reactive oxygen species generation and cumulative pregnancy rates was achieved in a cohort of patients for which the conventional semen profile per se was of no prognostic value. Furthermore, the patient population contained only 21 patients in whom high levels of reactive oxygen species generation were associated with low fertility (Table II). If only patients who exhibited oligospermia had been selected, then the proportion of samples that exhibited high levels of reactive oxygen species generation would have been considerably higher.[13] In addition, it must be remembered that lipid peroxidation is also dependent on the capacity of the spermatozoa or seminal plasma to scavenge reactive oxygen species as well as on the degree of exposure to free radical attack. Simultaneous measurement of defensive enzyme systems such as superoxide dismutase may therefore shed further light on the oxidative stress that is experienced by the spermatozoa, as might the direct measurement of lipid peroxides or conjugated dienes.

In summary, this article describes a unique data set in which the conditions for a valid assessment of new andrologic tests have been met in a prospective paradigm, which focused on the incidence of spontaneous pregnancy in a cohort of untreated couples in which a female factor has, as far as possible, been excluded. The results that were obtained indicate that sperm function tests, including assessments of sperm-oocyte fusion and reactive oxygen species generation, constitute a significant improvement over the conventional semen profile in the accurate assessment of male fertility.

The hemodynamic effects of intubation during nitroglycerin infusion in severe preeclampsia

Stephen Longmire, MD,[a] Line Leduc, MD,[b] Monica M. Jones, MD,[a] Joy L. Hawkins, MD,[a] Thomas H. Joyce III, MD,[a] and David B. Cotton, MD[b]

Houston, Texas

The effectiveness of intravenous nitroglycerin infusion in lowering maternal blood pressure and in blunting the hemodynamic responses to endotracheal intubation was evaluated in six primigravid women with severe preeclampsia. Monitoring consisted of continuous electrocardiogram monitoring, arterial cannulation, and flow-directed pulmonary arterial catheterization in each patient. All patients underwent oxytocin induction of labor and crystalloid and/or colloid expansion to produce a pulmonary capillary wedge pressure of 10 to 15 mm Hg and a colloid osmotic pressure of >17 mm Hg. Intravenous nitroglycerin was administered before induction of general anesthesia. The hemodynamic effects associated with endotracheal intubation revealed a change in the heart rate from 104 ± 10 to 133 ± 17 beats/min, an increase in mean arterial pressure from 134 ± 12 to 164 ± 32 mm Hg, and an increase in systemic vascular resistance from 1262 ± 342 to 1351 ± 259 dynes-sec-cm^{-5} that was accompanied by a small change in the cardiac index from 4.5 ± 1.2 to 4.5 ± 0.9 L · min^{-1} · m^{-2}. (Am J Obstet Gynecol 1991;164:551-6.)

Key words: Obstetric anesthesia, pregnancy-induced hypertension, intubation complications

The risks associated with the pressor response to endotracheal intubation in the general surgical patient have long been appreciated.[1-9] However, only recently has it been realized that this response may result in acute left ventricular failure, pulmonary edema, cerebral hemorrhage, and eclamptic seizures in the patient with severe pregnancy-induced hypertension.[4, 9-13]

Intravenous nitroglycerin has been recommended as an antihypertensive agent for use during endotracheal intubation in the treatment of severe preeclampsia.[14-16] Nitroglycerin would be expected to work well in a volume-contracted population such as that seen in this disorder. However, profound hypotension can be seen with the use of nitroglycerin in hypovolemic patients. To prevent abrupt and profound hypotensive re-

sponses that adversely affect uteroplacental blood flow during vasodilator therapy, we often volume-expand patients with severe preeclampsia. Volume expansion, however, may result in attenuation of the hypotensive action of a drug such as nitroglycerin, which is primarily a venodilator. We undertook this study to document the hemodynamic efficacy of intravenous nitroglycerin when used to control the circulatory responses to endotracheal intubation in volume-expanded patients with severe preeclampsia.

Material and methods

The Baylor College of Medicine Institutional Review Board for Human Investigation approved this study, and all patients gave written informed consent. Enrolled in this study and admitted to the obstetric intensive care unit were six patients with severe preeclampsia with a blood pressure of at least 160/110 mm Hg, accompanied by hyperreflexia and proteinuria (2+). The maternal age ranged from 17 to 20 years, and gestational age ranged from 32 to 41.5 weeks. None of these patients had received prenatal care. Left uterine displacement of at least 15 degrees was maintained throughout the study. These patients did not receive any medication other than magnesium sulfate (4 to 6 gm intravenous loading dose, 2 to 3 gm/hr maintenance infusion) and oxytocin before enrollment in the study. Oxytocin augmentation of labor was initiated when volume expansion was achieved.

Maternal systemic and pulmonary arterial pressures, central venous pressure, electrocardiogram, cardiac output, and uterine contractions, as well as fetal heart rate, were recorded on a Hewlett-Packard eight-channel physiologic recorder. Pressures were transduced with the Hewlett-Packard model 1290A quartz transducers, which were zeroed at the level of the right atrium. Radiographic verification of the position of the pulmonary artery catheter tip was established. Each pressure was measured with a Hewlett-Packard model 78231C cardiac output computer. Five determinations were made, each of which used 5 ml injections of 5% dextrose solution at 0° C. The highest and lowest values obtained were discarded, and the remaining three were averaged. To eliminate hypovolemia and low plasma colloid osmotic pressure as confounding variables and with the hope of preserving uteroplacental blood flow, patients received crystalloid such as lactated Ringer's solution and/or colloid (5% or 25% albumin). The goal of volume expansion was to achieve a pulmonary capillary wedge pressure of 10 to 15 mm Hg and a colloid osmotic pressure >17 mm Hg before endotracheal intubation during nitroglycerin infusions. Intravenous nitroglycerin was mixed in glass bottles of 5% dextrose in water and was infused via Travenol 2C9096 tubing with a calibrated infusion pump.

Baseline measurements were determined after arrival of the patient in the operating room. Infusion of intravenous nitroglycerin was begun at 0.1 μg/kg/min. The nitroglycerin infusion was titrated at 3-minute intervals until either a 20% reduction of the mean arterial pressure had been achieved or signs of fetal or maternal distress occurred.

Patients were then preoxygenated for a period of 10 minutes, during which time the infusion rate of the intravenous nitroglycerin was further titrated in an attempt to produce a further reduction of 20% in the mean arterial pressure. (Generally, this reduction could not be achieved because of the development of maternal nausea and vomiting.)

Induction measurements were made immediately before rapid-sequence intravenous induction-intubation, which was accomplished with thiopental 3 mg/kg and succinylcholine 100 mg. Maintenance anesthesia was provided with oxygen/nitrous oxide (4:4 L/min), halothane 0.5%, and succinylcholine 0.2% infusion. Laryngoscopy-to-intubation time did not exceed 33 seconds in any patient, and Miller 2 blades and 7.0 mm inner diameter cuffed endotracheal tubes were used throughout the study. The average duration between intubation and delivery was 4 minutes 38 seconds.

Intubation hemodynamics were measured as the endotracheal tube was inserted. The pulmonary artery catheter's balloon was briefly inflated, then deflated, and a single determination of the cardiac output was made. When the umbilical cord was clamped, morphine 200 μg/kg was given intravenously, the oxygen flow was reduced to 2 L/min, and the halothane was gradually discontinued.

Delivery measurements were made immediately after manual extraction of the placenta. A final set of measurements was made 30 minutes after surgical closure.

Intravenous nitroglycerin was considered to have been effective if the increase in blood pressure and/or heart rate did not exceed 20% of the baseline.

Data were analyzed with the one-way analysis of variance procedure in the SPSS/PC software package (SPSS Inc, Chicago). Multiple comparisons were tested for significance with Duncan's procedure.[17] In all cases significance was accepted at the $p < 0.05$ level. All data are reported as mean ± SD unless otherwise specified.[18]

Results

Mean maternal height and weight were 164.1 ± 3.8 cm and 82.4 ± 15.3 kg, respectively. The mean body surface area was 1.9 ± 0.19 m^2. The maternal hemodynamic effects observed at each interval are presented in Table I. Initial examination of the table appears to indicate that the original protocol was not followed. Indeed, the 20% reduction in mean arterial pressure

we hoped for was not present before intubation (no interval is significantly less than baseline). Close inspection of the protocol, however, reveals that our titration was limited by the development of either maternal nausea and vomiting or by fetal bradycardia in one case. Neonatal data are presented in Table II. All six patients exhibited progressively flattened beat-to-beat variability of the fetal heart rate recording. Whether magesium sulfate or nitroglycerin was responsible for the decrease in beat-to-beat variability remains unclear. In one patient fetal bradycardia necessitated stopping the infusion. In spite of the continuous presence of poor beat-to-beat variability, only neonate No. 1 had a 1-minute Apgar score <7. Neonate No. 5 had the highest umbilical venous methemoglobin concentration (4.6%) in the study. This neonate's mother had received one of the highest doses of intravenous nitroglycerin that was administered during the study (up to 30 μg/kg/min).

During initial titration, in four of six patients studied, nausea and vomiting developed and necessitated a reduction in the dose of intravenous nitroglycerin. None of these patients had experienced a 20% reduction in the mean arterial pressure before nausea and vomiting developed. Only one patient complained of a headache at the same time that nausea and vomiting occurred. Attempts to acutely reduce maternal mean arterial pressure in the operating room before induction of anesthesia were also characterized by maternal nausea, retching, and vomiting. The onset of nausea and vomiting did not appear to be related to the dose of nitroglycerin. In only two of six patients were we able to prevent an increase in mean arterial pressure >20% of baseline. Because of the high incidence of nausea and vomiting, coupled with an efficacy of only 33% in preventing an increase in mean arterial pressure that was >20% baseline, we terminated the protocol after only six of the projected 10 patients had been studied. All patients were delivered of infants by cesarean section. The indications for cesarean section were fetal bradycardia, (one case); cephalopelvic disproportion, (three cases); failure of induction, (one case); and worsening signs of HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), (one case).

Comment

In women with severe preeclampsia, induction of general anesthesia and endotracheal intubation significantly increase blood pressure, pulmonary arterial pressure, and pulmonary capillary wedge pressure. This response may precipitate any of several untoward events, including cardiac failure and pulmonary edema, cerebral edema, and/or hemorrhage.[9-13, 19] The reflex increase in the maternal heart rate and blood pressure that results from endotracheal intubation may play a role in the genesis of these complications. Indeed, a correlation between changes in mean arterial pressure that occurs during laryngoscopy and in plasma cate-

cholamine concentration has been previously observed.[20]

Several investigators have utilized multiple agents to decrease the blood pressure response associated with intubation. An ideal drug should be potent, rapidly acting, controllable, and without detrimental maternal or fetal side effects.

Hodginkson et al.[13] have previously shown that hydralazine (the most commonly used antihypertensive agent in severe preeclampsia) does not adequately control the brief but sudden episode of hypertension that occurs during intubation. The onset of action of hydralazine is too slow, and repetitive administration of hydralazine in an effort to control blood pressure may result in excess maternal hypotension and fetal distress.[21, 22]

Nitroprusside has also been used to control the hemodynamic changes associated with intubation. The potent and rapid onset of action, combined with no adverse effects on uterine blood flow,[15] support the use of this agent. However, nitroprusside can cause fetal toxicity in excessively large doses[23, 24] and can easily cause hypotension if not given carefully. Other potential maternal side effects include significant reflex tachycardia and the inhibition of cerebral autoregulation.[25] This latter effect predisposes a patient to elevations in intracranial pressure in cases of breakthrough hypertension. The appropriate role of nitroprusside in severe preeclampsia complicated by cerebral edema is still unclear.

Trimethaphan,[26] a ganglionic blocking drug, has limited use because of its slow onset and long duration of action. Furthermore, its inhibition of the action of pseudocholinesterase can prolong paralysis after succinylcholine administration. Also the mydriasis seen after trimethaphan administration makes neurologic assessment in complicated cases difficult.[26]

Labetalol,[27] a selective α_1-adrenergic receptor and a nonselective β-adrenergic receptor–blocking agent with intrinsic β_2-agonist activity, has been used in the treatment of patients with preeclampsia.[22, 27] Ramanathan et al.[27] reported that labetalol administration effected a moderate reduction in mean arterial pressure and tachycardic response to intubation in patients with mild to moderate preeclampsia. However, these authors were unable to achieve a 20% reduction in mean arterial pressure with labetalol before induction of anesthesia in 80% of patients because of a large variation in dose requirements among patients. They concluded that higher doses of labetalol might be needed in many patients. To date, no significant deleterious fetal effects have been reported to result from labetalol administration.

Nitroglycerin has been reported effective in controlling blood pressure in severe preeclamptic patients who undergo general anesthesia for cesarean section.[14-16] Our results contradict those obtained by Hood et al.,[16] who concluded that intravenous nitroglycerin was effective in controlling perioperative blood pressure. However, Hood et al.[16] were able to achieve nearly a 20% reduction of mean arterial pressure before induction of anesthesia, whereas we only achieved a mean reduction of 13%. In the study by Hood et al.,[16] other differences were that Hood's patients had received prenatal care, were significantly less hypertensive, and had not received volume loading before the administration of nitroglycerin. In addition, their patients received hydralazine during labor.

We defined a therapeutic failure as any increase in heart rate or blood pressure of >20% over baseline. With this definition, maximal therapy with intravenous nitroglycerin failed to control the heart rate in all patients in our study. Intravenous nitroglycerin failed to control blood pressure in 66% of the patients, and the

dose used was of no value in predicting the ability to control blood pressure during intubation. A possible explanation for our failure to achieve the desired 20% reduction in mean arterial pressure was that our patients were all volume-expanded (Table III), as opposed to those of Hood et al.[16] In our study we volume-expanded patients to maintain an adequate maternal cardiac output and therefore to preserve the uteroplacental blood flow while reducing blood pressure. This approach also eliminated hypovolemia and low colloid osmotic pressure as confounding variables in an already complex investigation.

In agreement with our previous published data, it seems that volume expansion blunts the action of nitroglycerin, since the agent primarily affects the venous capacitance and ventricular preload.[28] We did, however, prevent a 20% increase in mean arterial pressure at the time of intubation in 33% of the patients. Nevertheless, the mean value for the study group of 164 ± 32 mm Hg was substantially more than the 140 mm Hg level that has been associated with loss of cerebrovascular autoregulation.[25] This raises a concern regarding the use of intravenous nitroglycerin to treat severe preeclampsia complicated by cerebral edema.

The most common side effects of intravenous nitroglycerin treatment reported by our patients were nausea and vomiting. The diluent used in preparation of intravenous nitroglycerin contains 70% ethanol,[29] which may have contributed to the development of these symptoms. Furthermore, an increase in intracranial pressure related to nitroglycerin might explain these side effects, although only one patient complained of headache during nitroglycerin infusion.

Our patients were monitored in the obstetric intensive care unit, where the infusion of intravenous nitroglycerin was initiated before surgery. Fetal heart rate monitoring was used in every case. The flattening of the beat-to-beat variability reported in our patients could be related to nitroglycerin infusion. It is unlikely, however, that these fetal heart rate changes indicated chronic fetal distress, since none of the umbilical cord gas levels showed a pH <7.25 and only neonate No. 1 had a 1-minute Apgar score <7.

It is of interest that central venous and pulmonary artery pressures increase with delivery of the placenta, while blood pressure decreases transiently. We speculate that the increase in venous return to the heart is secondary to a shift of blood from the uterus to the intravascular space, the release of caval compression from the gravid uterus, and mobilization of extravascular fluid into the intravascular compartment. This probably accounts for the increase in the central venous pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure seen at the time of delivery.

In summary, we found that intravenous nitroglycerin was not effective in controlling the hypertensive response to endotracheal intubation in our population of volume-expanded patients with severe preeclampsia. Given the highly variable responses to intravenous nitroglycerin as an antihypertensive agent, we conclude that the routine use of intravenous nitroglycerin to combat the hypertensive response to endotracheal intubation in patients with severe preeclampsia may not be warranted if the patient has been previously volume-expanded. In patients who are volume-contracted with severe preeclampsia, nitroglycerin may still be a useful agent for the control of hypertension.

Vasoactive intestinal polypeptide loses its ability to increase vaginal blood flow after menopause

Connie Palle, MD,[a] Helle E. Bredkjær, MD,[a] Jan Fahrenkrug, PhD,[a] and Bent Ottesen, PhD[b, c]

Copenhagen, Denmark

The effect of vasoactive intestinal polypeptide on vaginal blood flow was investigated in postmenopausal women. In women who were receiving hormonal replacement therapy the vasodilatory response induced by vasoactive intestinal polypeptide was identical to that of young women, whereas in postmenopausal women who were receiving no replacement therapy, the response induced by vasoactive intestinal polypeptide was absent. Plasma levels of vasoactive intestinal polypeptide and systemic cardiovascular effects were identical in the two groups. (AM J OBSTET GYNECOL 1991;164:556-8.)

Key words: Vasoactive intestinal polypeptide, vaginal blood flow, postmenopausal women, hormonal replacement therapy

In the female genital tract vasoactive intestinal polypeptide is regarded as a neurotransmitter involved in the control of blood flow, motility, and secretion.[1] Exogenous vasoactive intestinal polypeptide has been shown to increase vaginal blood flow and lubrication in fertile, nonpregnant women to a level similar to that observed during sexual arousal.[2] In the present study, we investigated the vasodilatory effect of vasoactive intestinal polypeptide in two groups of postmenopausal women. The first group included six women (age [mean ± SEM], 58 ± 1 years; body weight, 66.0 ± 5.7 kg; duration of menopause, 7.7 ± 2.6 years) who were receiving no medication at all. The second group consisted of six postmenopausal women (age, 54 ± 1.2 years; body weight, 61.0 ± 4.4 kg) who were receiving hormonal replacement therapy for climacteric symptoms. Five of the women had therapy including both estrogen and gestagen, whereas one woman who had had a hysterectomy received only estrogen. The average time of treatment was 4.3 ± 1.4 years. All women gave informed consent after the study was approved by the local ethical committee of Copenhagen, Denmark.

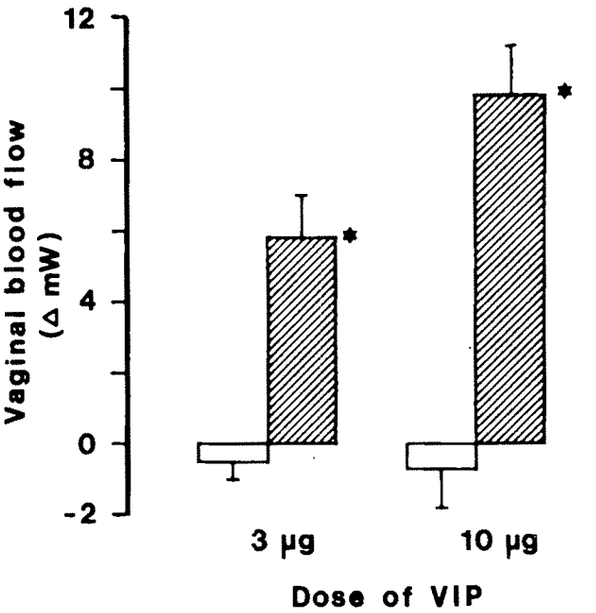

Fig. 1. Effect of vasoactive intestinal polypeptide on vaginal blood flow in postmenopausal women receiving no medication *(open bars)* and in postmenopausal women receiving hormonal replacement therapy *(hatched bars)*. Figures are given as means ± SEM (n = 6). Infusion of saline solution did not change vaginal blood flow (not shown). *VIP*, Vasoactive intestinal polypeptide. *Asterisks* indicate significant difference from before injection of vasoactive intestinal polypeptide, $p < 0.05$.

Local vaginal blood flow was continuously measured by a heated oxygen electrode (TMC 2, Radiometer, Copenhagen, Denmark),[3] that was placed on the right side of the vaginal wall, approximately 5 cm from the introitus. The electrode was kept in place by a slight vacuum. The vaginal blood flow was measured by the energy (in milliwatts) needed to maintain the electrode at a constant temperature (42° C). The change in energy is proportional to the change in vaginal blood flow. The blood flow changes are given as the increase or decrease in milliwatts and were recorded on a TMC 2 pen recorder (Radiometer). The basal vaginal blood flow was measured for 30 minutes, whereupon synthetic human vasoactive intestinal polypeptide (Peninsula Laboratories, St. Helens, United Kingdom) dissolved in isotonic saline solution and then sterile filtered was administered as intravenous injections in doses of 0, 3, and 10 μg in one arm. From the other arm, blood samples were collected (1, 2, 3, 4, 5, and 10 minutes after the injections) for analysis of vasoactive intestinal polypeptide by radioimmunoassay. Blood pressure and pulse frequency were monitored throughout the experiment.

In the untreated group of women vasoactive intestinal polypeptide was unable to increase vaginal blood flow, whereas in the hormone-treated group of postmenopausal women a significant ($p < 0.05$; Mann-Whitney u test) increase in vaginal blood flow was observed after intravenous injection of both 3 and 10 μg of vasoactive intestinal polypeptide (Fig. 1). No difference was observed in basal vaginal blood flow between the two groups (untreated group, 135 ± 3 mW; treated group, 133 ± 4 mW). The two groups showed identical increments in plasma vasoactive intestinal polypeptide concentrations. After intravenous injection of 10 μg of vasoactive intestinal polypeptide, the peak concentrations in the untreated and the hormone-treated group were 151 ± 32 pmol/L and 96 ± 18 pmol/L, respectively, values that were not significantly different. Basal concentrations were <20 pmol/L in all women. Systemic cardiovascular side effects (i.e., diastolic hypotension, tachycardia, and cutaneous flushing localized to the face and upper trunk) were observed to the same extent in the two groups of women (Table I).

The present study indicates that vasoactive intestinal polypeptide loses its ability to increase vaginal blood flow after menopause. However, when women were treated with sex hormones, the vasodilatory effect seemed to be maintained or returned to a level that corresponded to that of fertile women. It has been suggested that vasoactive intestinal polypeptide is involved in the physiologic vasodilation and vaginal lubrication that take place during sexual arousal. Vaginal dryness is a common problem in postmenopausal women, and it is well known that estrogen improves this symptom. The function of the vascular vasoactive intestinal polypeptide receptor in the vagina seems to depend on the presence of sex hormones, and the mechanism may be that sex hormones accelerate the synthesis of the vasoactive intestinal polypeptide receptor. However, the systemic cardiovascular effects of vasoactive intestinal polypeptide were unaffected in postmenopausal women. In agreement with our results, it was recently discovered that vasoactive intestinal polypeptide loses its prolactin-releasing activity in postmenopausal

women.[4] The interaction among vasoactive intestinal polypeptide, its receptor, and sex hormones in the female reproductive system must be further elucidated.

Analysis of antigen expression at multiple tumor sites in epithelial ovarian cancer

Stephen C. Rubin, MD, Connie L. Finstad, PhD, William J. Hoskins, MD, Diane Provencher, MD, Mark G. Federici, BS, Kenneth O. Lloyd, PhD, and John L. Lewis, Jr., MD

New York, New York

The question of whether the antigenic phenotype of human epithelial ovarian cancer varies in a given patient between the primary tumor and metastatic sites or among metastatic sites themselves is an important issue in planning potential therapeutic strategies for ovarian cancer. We have obtained tumor specimens from at least two separate sites during operations on 12 patients with epithelial ovarian cancer, and we have typed these specimens with a group of 18 monoclonal antibodies that react with cell-surface glycoprotein and carbohydrate antigens, including blood group antigens. Antibodies with relative specificity for malignant cells as well as those that detect more widely distributed epithelial antigens were used. A total of 31 specimens from 12 patients with advanced adenocarcinoma (8 serous, 3 undifferentiated, 1 endometrioid) of the ovary were studied, including fresh ascites cells in two patients. Frozen sections of tumor specimens were stained with the antibodies by the indirect immunoperoxidase technique and graded semiquantitatively. Little difference was seen in antigenic expression of tumors that were obtained from various sites in the same patient for either the epithelial cell markers or blood group markers. Intratumoral antigenic heterogeneity was seen, but this was generally quite consistent within a given patient's specimens. As anticipated, variations in antigen expression were seen among specimens from different patients. The antigenic phenotype of the tumor specimens in a given patient, as determined immunohistochemically by our group of antibodies, showed only minor variation among primary and metastatic sites. (Am J Obstet Gynecol 1991;164:558-63.)

Key words: Ovarian cancer, immunology, antigen expression, antigenic heterogeneity

The development of monoclonal antibody technology has led to accelerated activity in the field of tumor immunology and increased the possibility that antibodies may one day play an important role in the management of cancer. In the field of gynecologic oncology a major portion of this activity has related to ovarian cancer for which there is a pressing need for improvements in early diagnosis, monitoring of response, and treatment. Many antibodies that react with ovarian cancers have been identified,[1] serum markers have come into clinical use,[2, 3] and preliminary studies of tumor imaging and therapy with monoclonal antibodies have been reported.[4] In spite of these efforts, many questions that relate to the clinical usefulness of antibodies remain unanswered. Among the major questions is the extent to which antigen expression varies between the primary tumor and metastatic sites and among meta-

static sites themselves. This issue, which has significant implications regarding the selection of antibodies for clinical use, is of particular importance in ovarian cancer because most patients with ovarian cancer present with tumor that has spread to multiple metastatic sites. If a single sample of a patient's tumor is characterized antigenically, can it be assumed that tumor in other locations will show similar antigenic expression? To address this question we have obtained tumor specimens from several sites in a group of patients with ovarian cancer and studied these specimens with a panel of monoclonal antibodies that represent a spectrum of cell-surface glycoprotein–related, carbohydrate-related, and blood group–related antigens, some with relative specificity for malignant cells and others with a wider distribution of reactivity.

Patients and methods

Antibodies. Monoclonal antibodies MH99, T16, MW162, MW207, MX35, MT334, T174, T218, P12, 118, F3, T36, and S8 were generated and characterized in our laboratory. They are described in Table I and referenced fully in previous publications.[5] The monoclonal antibody RAI-15 was a gift from Dr. R. Ueda of Nagoya, Japan; OC125 was obtained from Dr. R. Bast of Duke University; B72.3 was obtained from Dr. J. Schlom of the National Cancer Institute; 19.9 was purchased from Centocor (Malvern, Pa.); and E29, which detects epithelial membrane antigen, was purchased from Dako Corp. (Santa Barbara, Calif.).

Immunohistochemical analysis. Tumor specimens were obtained at the time of laparotomy in 12 patients with epithelial cancer of the ovary. Specimens were obtained from three different tumor sites in five women and from two different sites in the remaining seven women. All metastatic tumor was obtained from sites within the peritoneal cavity. Additionally, tumor cells were obtained from ascitic fluid in two women after lysis of erythrocytes and centrifugation of the remaining cells. Tissue specimens and ascites cell pellets were frozen in liquid nitrogen, embedded in OCT compound, and stored at −70° C until they were sectioned. Frozen sectons were cut at 6 μm, fixed with acetone and paraformaldehyde, and treated with 1% hydrogen peroxide to eliminate endogenous peroxidase activity. Sections were stained with preparations of monoclonal antibodies (concentration of 20 μg/ml) by the indirect immunoperoxidase technique with diaminobenzidine as the chromogen and hematoxylin as a counterstain. Detailed methods have been described previously.[5] Sections were examined with a light microscope, and the antibody staining patterns for the approximately 700 sections were scored in a semiquantitative fashion by one person.

To test for heat stability of the antigens, antibodies were incubated for 1 hour at 4° C with a pellet of a

human cancer cell line that showed positive antibody reactivity or with the cell pellet after it had been boiled (100° C) for 5 minutes. The two samples of absorbed monoclonal antibodies were tested for reactivity by immunohistochemistry and were compared with the reactivity of the same unabsorbed monoclonal antibody. Monoclonal antibodies that detected heat-stable antigens showed no reactivity on tissue sections after absorption with a boiled cell pellet.

To test for carbohydrate epitopes that are sensitive to periodate treatment, tissue sections were fixed with acetone and paraformaldehyde, exposed to hydrogen peroxide as described above, and then incubated in 0.05 mol/L sodium acetate, pH 6.0 with or without 0.02 mol/L sodium periodate for 2 hours at room temperature. After sections were washed with phosphate-buffered saline, the immunohistochemical analysis was continued as described.

To test for the presence of sialic acid-containing epitopes, tissue sections were fixed with acetone and paraformaldehyde, exposed to hydrogen peroxide as described, and then digested with *Vibrio cholerae* neuraminidase (0.1 U/ml) in phosphate-buffered saline that contained Ca^{++} and Mg^{++} at pH 7.0 for 90 minutes at 37° C. After sections were washed with phosphate-buffered saline, the immunohistochemical analysis was continued as described.

Results

The clinical characteristics of the patients, the specimens that were studied, and the histologic features of the tumors are shown in Table II. In general, the antigenic phenotypes that were observed in this study had no correlation with tumor grade and histologic cell type. Most significantly, almost no variation was seen in antigen expression among specimens that were obtained from various sites in the same patient for either the cell-surface markers or blood group markers (Tables III and IV). Intratumoral antigenic heterogeneity (variation in antigen expression from area to area with an individual tumor specimen) was observed with monoclonal antibodies that detect carbohydrate determinants, whereas antibodies that detect protein epitopes showed minor or no variation in antigen expression. Even in tumors that stain heterogeneously, however, comparison of antigenic phenotypes among primary and metastatic sites, including tumor cells from ascitic fluid, showed only minor differences in the percentage of cells that stained positive. Thus within a given patient's specimens, the antigenic phenotype was quite consistent from site to site with this antibody group. As anticipated, variations were seen in antigen expression in tumors from different patients.

All of the epithelial ovarian cancer specimens that were examined in this study expressed MH99, MW162, and epithelial membrane antigens on the majority of tumor cells. Specimens from some patients also expressed CA125, MX35, and MW207 antigens with a homogeneous staining pattern. However, areas of variable staining were noted in specimens from some patients with OC125, MX35, and MW207 antibodies; this heterogeneous staining could not be correlated with tumor grade or histologic cell type of the tumor. Periodate treatment or sialidase digestion of these tumor specimens before immunohistochemical staining also did not alter the pattern of reactivity, which suggests that the epitopes that were detected by these monoclonal antibodies were not carbohydrate in nature. In contrast, monoclonal antibody B72.3 detects a periodate-sensitive epitope. Recent studies,[6, 7] have shown that the epitope that is recognized by monoclonal antibody B72.3 is sialyl-Tn (TAG72). Five of the 12 patients who were studied had moderately high expression of TAG72 in tumors, and at least 70% of tumor cells showed a luminal pattern of reactivity. In contrast, only minor populations of cells (1% to 10%)

stained positive with monoclonal antibody MT334 in samples from five patients. The epitope that was detected by monoclonal antibody MT334 is a combined carbohydrate-protein structure that is carried on a mucin[8] (unpublished results).

Blood group–related antigens showed variation in expression in samples from different individuals. Three of the 12 patients had blood type A. Specimens from two of these patients retained the A blood group type of the patient, whereas in the other patient A antigen was not detected in the tumor. Nine of the 12 patients had blood type O (H). Specimens from one patient with blood type O retained strong H expression in an endometrioid-type ovarian carcinoma; H antigen expression was heterogeneous in the samples from six patients with serous or undifferentiated tumors and undetectable in the remaining two, which were samples from serous tumors. In a metastatic lesion from one patient (N.A.) with a primary tumor that stained heterogenously, loss of ABH antigen expression was observed in areas in which the tumor cells were poorly differentiated. However, in another patient (S.G.) with a poorly differentiated tumor, there was a strong homogeneous pattern of A antigen expression in both of the metastatic lesions that were tested.

Intratumoral heterogeneity was also observed with

the Lewis blood-group antigens Le^a, sialyl-Le^a, and Le^b, and histologically similar areas within a specimen showed similar patterns of reactivity. In most instances all three antibodies were either positive (3 of 12 patients) or negative (7 of 12 patients) within a specific tumor area. In two cases, only Le^a and sialyl-Le^a were detected. These results suggest the possibility that ovarian tumors could be subclassified on the basis of Lewis antigen expression, but this observation and its clinical significance require further study.

Comment

In this study we found remarkably little variation in the antigenic expression of epithelial ovarian cancer among primary and metastatic sites in the same patient with the use of a group of monoclonal antibodies to detect a spectrum of cell-surface antigens. The only exception to this observation was the loss of expression of Le^a and sialyl-Le^a in metastatic tumor from a single patient. In two patients (S.G., A.O.) no primary tumor was tested; antigen expression was essentially identical between two metastatic sites for each of these patients. These findings are consistent with previous work from this laboratory,[5] which showed no significant variation over time in the antigen expression of ovarian tumors that were sampled at sequential operations in individual patients, and confirm the findings in a recent report by Berchuck et al.[9] that employed a smaller group of

antibodies to evaluate antigen expression among primary and metastatic sites in epithelial ovarian cancer.

A number of additional observations can be made regarding antigen expression in epithelial ovarian cancer. The secretion of mucins and high molecular weight glycoproteins, such as CA125, is characteristic of epithelial ovarian cancers. Several of the antibodies that we have studied react with the carbohydrate on these mucins. For example, one antibody (B72.3) detects sialyl-N-acetylgalactosaminyl serine or threonine (i.e., O-linked chains). Others detect the blood group–related determinants Le^a, Le^b, and sialyl Le^a, which can be either O-linked or linked to asparagine (i.e., N-linked chains) in glycoproteins. The antigens A, B, and H, and Lewis antigens can also be carried on glycolipids. It is of interest that the serous papillary tumors often showed a reciprocal staining pattern between B72.3 and anti-Lewis antibodies (Tables III and IV). This observation suggests a possible explanation for one aspect of intratumoral heterogeneity and suggests that a particular tumor tends to synthesize characteristic carbohydrate structures. Nakasaki et al.[10] similarly suggested that the intratumor antigenic mosaicism that is found in colonic and gastric cancers is due to cell populations that display different degrees and types of glycosylation. In a single patient (J.S.), there appeared to be a loss of Lewis antigen expression in the metastatic tumor, which was somewhat less well differentiated than the primary tumor. Such loss of blood group antigen expression has been associated with increased invasiveness in cancers of the urinary bladder.[11]

One might have expected considerable antigenic diversity to be present in ovarian cancer specimens from different sites, given the degree of intratumoral heterogeneity that was demonstrated in this and our previous study,[5] our current concept of the spread of this cancer, and the fact that considerable variation in antigen expression has been demonstrated in other tumor systems.[10, 12-14] It is possible, of course, that differences may exist in the expression of antigens that were not examined in this study. We have, however, included a number of antibodies with patterns of reactivity on ovarian cancers and normal tissues that make them important candidates for clinical use, such as OC125, B72.3, MX35, and MH99. The consistent expression among primary and metastatic sites of the antigens that are detected by these antibodies encourages the continued search for clinical applications for monoclonal antibodies in patients with ovarian cancer.

Reproducibility of the oral glucose tolerance test in pregnancy

Frederick E. Harlass, MD,* Kim Brady, MD, and John A. Read, MD
Tacoma, Washington

This prospective investigation evaluated the reproducibility of the 100 gm oral glucose tolerance test. Sixty-four obstetric patients with ≥135 mg/dl on the 50 gm oral glucose screening test were scheduled for the 100 gm test. All patients repeated the oral glucose tolerance test in 1 to 2 weeks. Both tests included a preparatory diet, and testing conditions were identical. There were no significant differences in the mean test values at each testing interval when the entire study population was considered. Patients were then divided into four groups according to the outcome of the two tests. Forty-eight of 64 (75%) had normal results at each testing period (group 1); 11 of 64 (17%) had initially normal results and abnormal results on retest (group 2); 3 of 64 (5%) had initially abnormal results and normal results on retest (group 3); 2 of 64 (3%) had abnormal results at both testing phases (group 4). There were no significant differences between oral glucose tolerance test results within groups 1 and 4. However, significant differences occurred within groups 2 and 3 between the two tests. Group 2 patients had a greater frequency of an abnormal 1-hour value on the test than group 1 patients ($p = 0.001$). Overall, the reproducibility of the oral glucose tolerance test was 78% (50 of 64). We recommend the oral glucose tolerance test be repeated when the 1-hour value is abnormal or when the fasting blood sugar, 1-hour, and 2-hour values are near the upper end of the normal range. (AM J OBSTET GYNECOL 1991;164:564-8.)

Key words: Oral glucose tolerance test, pregnancy, reproducibility

O'Sullivan and Mahan[1] defined the abnormal glucose tolerance test (GTT) on the basis of data obtained from 752 asymptomatic pregnant patients. With the use of the 100 gm oral glucose load, the mean and 2 SDs defined the upper limits of normal at each hourly testing period. These criteria have been shown to have physiologic significance for predicting future diabetes and perinatal morbidity and mortality.

As recommended by the Second International Workshop Conference[2] on Gestational Diabetes, all pregnant women should be screened for glucose intolerance between 24 and 28 weeks' gestation. Any patient with a venous plasma glucose value >140 mg/dl should have the full diagnostic glucose tolerance test.

In the nonpregnant population, the reproducibility of the 3-hour oral GTT has been evaluated. Rushforth et al.[3] investigated the reproducibility of the test in a population of 61 nonpregnant Pima Indians. These patients were given two oral GTTs 1 to 3 weeks apart. They found a mean difference of 30.1 mg/dl for the 1-hour value and 22.3 mg/dl for the 2-hour value of the oral GTT. Hence, there was considerble disagreement in the classification of persons as to their diabetic status. These results are consistent with other investigations reported in the literature.[4-8]

To our knowledge, the reproducibility of the oral GTT during pregnancy has not been investigated. The purpose of this prospective investigation is to determine the reproducibility of the 100 gm oral GTT in pregnancy.

Material and methods

This prospective investigation was conducted at Madigan Army Medical Center between September 1, 1987, and December 31, 1987. This institution serves a population composed principally of dependents of Army enlisted personnel. The mean family income is $11,000 to $16,000. All patients have unrestricted access to medical care, and no direct monetary payment is required for any physician or ancillary service. Madigan Army Medical Center is a tertiary care center that receives referrals from other military installations. Our obstetric population comprises 72% white, 16% black, 5% Hispanic, 5% Oriental, and 2% other patients.

All obstetric patients at Madigan Army Medical Center undergo the 1-hour, 50 gm oral glucose screening test. This test is performed at the initial obstetric visit if risk factors for gestational diabetes mellitus including age >25 years, obesity, history of macrosomia, previous stillborn fetus, or a family history of diabetes mellitus are present. In the absence of risk factors, all patients are screened at 24 to 28 weeks' gestation with the oral glucose screening test including patients who had normal test results at their initial obstetric visit.

If the threshold on the 50 gm oral glucose screening

Table I. Mean (±SD) glucose values on the oral GTT for each testing period

Test interval	*Test period*			*Pearson's correlation coefficient*	
	1	*2*	*p Value*	*r*	*p Value*
Fasting	90 ± 14	87 ± 10	NS	0.2	NS
1-Hour	162 ± 36	162 ± 36	NS	0.3	.001
2-Hour	138 ± 26	136 ± 28	NS	0.0	NS
3-Hour	113 ± 30	114 ± 31	NS	0.0	NS

test is ≥135 mg/dl, the patient is scheduled for a 100 gm oral GTT. The patients are requested to consume a diet of at least 150 gm of carbohydrate per day for 3 days before the test. The test preparation and performance is in accordance with the Second International Workshop Conference on Gestational Diabetes. The diagnosis of gestational diabetes mellitus is made when two or more venous plasma glucose concentrations meet or exceed the following blood sugar levels: fasting level of 105 mg/dl; 1-hour of 190 mg/dl; 2-hour of 165 mg/dl; and 3-hour of 145 mg/dl.[2] Patients who meet the criteria for gestational diabetes mellitus are admitted to the hospital for dietary or dietary and insulin management. Patients are then followed up through the complicated obstetric clinic to ensure adequate control and compliance.

Sixty-four obstetric patients who were scheduled for the oral GTT were enrolled in the investigation. A second oral GTT was performed in approximately 1 to 2 weeks. Test preparation and performance conditions were identical between the two testing periods. Fasting blood sugar levels were obtained between 8 and 9 AM. Patients were allowed to ambulate; however, they were not allowed to eat, smoke, drink any beverage other than water, or exercise. Any patient who did not tolerate the glucose solution was removed from the investigation. Patients were then divided into one of four groups, depending on the results of the two oral GTTs. The four groups were as follows: patients in group 1 had a normal oral GTT results followed by normal oral GTT results, group 2 patients had a normal results followed by abnormal results, group 3 patients had abnormal results followed by normal results, and group 4 patients had abnormal results followed by abnormal results. In addition, the reproducibility within the four groups was evaluated by the trimester in which the tests were performed.

Significance of continuous data was assessed by the Student *t* test for paired data. Statistical analysis of discrete data was performed with χ^2 analysis or Fisher's exact test. Pearson's correlation coefficient *(r)* was calculated for paired responses at each testing interval of the oral GTT with Lotus 123 (Lotus Development Corporation, Cambridge, Mass.). A probability value of <0.05 was considered significant.

Results

The mean age of the study population was 27 ± 5.6 years; 22 were nulliparous. Forty-eight of 64 (75%) patients had normal results at both testing periods (group 1). Eleven of 64 (17%) were normal at the initial period, but abnormal at repeat testing (group 2). Three of 64 (5%) patients were abnormal at the initial testing period, but normal at retesting (group 3). Two of 64 (3%) patients had abnormal results at both testing periods (group 4). Table I shows the mean oral GTT values at each interval for the entire population. There were no statistically significant differences between the two testing periods. In addition, only the 1-hour value during the two testing periods was significantly associated.

Table II shows the oral GTT values at each testing period when evaluated by groups. There was no significant difference between tests within groups 1 (normal-normal) and 4 (abnormal-abnormal). However, significant differences occurred between tests within groups 2 (normal-abnormal) and 3 (abnormal-normal). Between groups 1 (normal-normal) and 2 (normal-abnormal), there were significant differences in the mean plasma glucose values at fasting and at 1-hour and 2-hour test intervals ($p = 0.02$, $p = 0.003$, $p = 0.02$, respectively). Table III compares the number of patients in group 1 (normal-normal) with the number of patients in group 2 (normal-abnormal) who had one of four values that met or exceeded the limits on the oral GTT. Of note, 55% (6 of 11) of patients in group 2 had an abnormal 1-hour value and 72% (8 of 11) of patients in group 2 had one abnormal value compared with only 17% (8 of 48) of patients in group 1. Of the two groups (groups 3 and 4) that had abnormal initial test results, only two of five (45%) were reproducible. Moreover, 48 of 59 (81%) of patients with normal initial results had reproducible tests.

There were no significant differences between trimesters in the reproducibility of the oral GTT ($p = 0.4$). Twelve patients had the tests performed in the first trimester, all of which were reproducible. Of the 42 patients who were evaluated in the second trimester, 31 (74%) were reproducible. Seven of ten (70%) patients who were evaluated in the third trimester had reproducible tests. In our population, significantly

Table III. Distribution of patients with one abnormal value on the oral GTT in groups 1 and 2

Test interval	*Group 1 (normal-normal)*		*Group 2 (normal-abnormal)*		*p Value*
	Frequency	*%*	*Frequency*	*%*	
Fasting	1/48	2	1/11	9	NS
1-Hour	4/48	8	6/11	55	0.001
2-Hour	1/48	2	1/11	9	NS
3-Hour	2/48	4	0/11	0	NS
TOTAL	8/48	17	8/11	72	0.0007

more patients had normal initial results with abnormal retest results ($n = 11$) than abnormal initial results with normal retest results ($n = 3, p = 0.04$). The reason for the difference is not apparent. The difference may be a result of an α error inasmuch as there were no significant differences between the two groups in demographic data (age, parity, or weeks' gestation at each testing phase). Overall, 50 of 64 (78%) oral GTTs were reproducible (groups 1 and 4 of groups 1, 2, 3, 4). The mean birth weight of group 1 (normal-normal) was 3525 gm, which was not significantly different from group 2 (normal-abnormal, 3589 gm), group 3 (abnormal-normal, 4096 gm), and group 4 (abnormal-abnormal, 3677 gm).

Comment

The clinical value of a test depends greatly on its reliability. In addition, the diagnostic value of any test is determined by its ability to discriminate normal from abnormal in comparison to its susceptibility to intraindividual variation. It is well recognized that gestational diabetes mellitus is associated with an increased incidence of maternal and fetal complications. Therefore the accurate diagnosis of gestational diabetes mellitus is important. In both pregnant and nonpregnant populations, the oral GTT has represented the cornerstone in the diagnosis of gestational diabetes mellitus. Unfortunately, there is no "gold standard" by which to judge the accuracy of the oral GTT.

Troxler et al.[9] investigated the oral GTT by 11 different criteria in a nonpregnant population and was able to show a reproducibility of only 50%. McDonald et al.[6] performed six 100-gm, 3-hour oral GTTs on 334 asymptomatic male volunteers. They documented a variation of ±34 mg/dl at the 1-hour interval over the six tests. Among the six tests, a number of patients varied from normal test results to having a test diagnostic of diabetes mellitus. In a related investigation on the reproducibility of the 50-gm, 1-hour glucose screening test, Sacks et al.[10] found that the screening test was only "moderately reproducible." With the use of a single screening test with the test value ≤135 mg/dl, they would have missed 27% of the diabetic population. Because of the marked variability that may be encountered in oral GTTs in the nonpregnant population, Nelson[11] has stated that unless the test is grossly abnormal, it should be performed on two occasions before diabetes mellitus is diagnosed.

In most populations, plasma glucose values are continuous measurements with a unimodal distribution. Irrespective of the values chosen for the limit of normal on the oral GTT, some patients with gestational diabetes mellitus will be falsely classified as normal and others without gestational diabetes mellitus will be misclassified as having gestational diabetes mellitus. If one considers that it is more important to overdiagnose gestational diabetes mellitus than to not diagnose the disease when it is present, the important group to consider

Interval							
2-Hour				3-Hour			
Initial	*Repeat*	*p Value*	*r*	*Initial*	*Repeat*	*p Value*	*r*
131	129	NS	0	110	107	NS	0
147	169	‡	0	111	145	‡	0.1
189	105	‡	1	182	97	‡	1
185	172	NS	‖	138	129	NS	‖

in our investigation is group 2 (e.g., those who had normal initial oral GTT results, but on retesting had abnormal results). In this clinical situation, the patient would be followed-up more closely with diet therapy (with or without insulin) and fetal heart rate testing. However, if one considers that it is more important to NOT overdiagnose gestational diabetes mellitus, the important population to consider is group 3 (e.g., those who had abnormal initial oral GTT results, but on retesting had normal results). Most clinicians would rather risk overdiagnosis of gestational diabetes mellitus and provide the patient with closer surveillance.

The mean plasma oral GTT values for groups 1 and 2 were within the normal range. However, our investigation showed significant differences in the mean plasma glucose values at the fasting, one-hour, and two-hour intervals on the oral GTT in those patients who had normal oral GTT results followed by abnormal oral GTT results (group 2) when compared with patients with two normal oral GTT results (group 1). Because the majority of laboratories use the glucose oxidase method to measure plasma glucose, Carpenter and Coustan[12, 13] recommend use of a fasting value of 95 mg/dl, a 1-hour value of 180 mg/dl, a 2-hour value of 155 mg/dl, and a 3-hour value of 140 mg/dl as representative of the threshold values of the oral GTT. In addition, a recent investigation by Sacks et al.[14] further supports the concept that the currently accepted values on the oral GTT may be too high. They recommend a fasting threshold value of 96 mg/dl, a 1-hour value of 172 mg/dl, a 2-hour value of 152 mg/dl, and a 3-hour value of 131 mg/dl. These values agree with Carpenter and Coustan's values and the values (mean ± 1 SD) we obtained in group 1 patients.

Significantly more patients in study group 2 (normal-abnormal) had one abnormal oral GTT value than in group 1 (normal-normal) patients (8 of 11 versus 8 of 48, respectively, $p = 0.0006$). The most frequent abnormal value on the oral GTT was the 1-hour value (Table III). Ten of 59 (17%) patients (groups 1 and 2) had initially normal oral GTT results with an abnormal 1-hour value. On repeat testing, 6 of the 10 patients had oral GTT results diagnostic of gestational diabetes mellitus. The mean birth weight of infants born to mothers in groups 2, 3, and 4 was not significantly different from those in group 1. We believe this is attributable to therapeutic intervention of group 2 (diet therapy and insulin if necessary).

The results of our investigation show a significant variability in oral GTT results when glucose values are in the upper-normal range. In many cases, this variability was sufficiently large to reclassify the patient as having gestational diabetes mellitus. In summary, we recommend the oral GTT be repeated if the patient has an abnormal 1-hour value or the fasting, 1-hour, and 2-hour oral GTT values are normal but elevated.

Steroid-responsive nephrotic syndrome with renal insufficiency in the first trimester of pregnancy

Luis G. Uribe, MD, Vashu D. Thakur, MD, and N. Kevin Krane, MD
New Orleans, Louisiana

Successful treatment of a woman with renal failure due to presumed minimal change nephropathy in the first trimester of pregnancy is presented. (Am J Obstet Gynecol 1991;164:568-9.)

Key words: Nephrotic syndrome, pregnancy, renal insufficiency

We report a case of renal insufficiency and severe nephrotic syndrome that was diagnosed and treated in the first trimester of a woman who was first seen with severe edema. Minimal change nephropathy was the presumptive diagnosis, and although this entity has been reported in pregnancy, its presentation with renal failure makes this a particularly unusual case.[1]

A 22-year-old black woman, gravida 2, para 1, abortus 0, was seen at 18 weeks' gestation with a 2-day history of swelling in her legs and a 3-day history of influenza-like symptoms for which she was given penicillin. The patient had a history of nephrotic syndrome since age 5 years and had received prednisone therapy on at least three occasions, the last course being 2 years before this admission to the hospital. During her most recent relapse, the patient had hypertension, edema, and a rise in her serum creatinine level, all of which resolved with steroid therapy.

On physical examination, the blood pressure was 110/70 mm Hg, fundal height was consistent with 18 weeks' gestation, and there was 2 to 3+ pitting edema up to the knees. The white blood cell count was 5200/mm^3, hemoglobin 9.5 gm/dl, hematocrit 32.1%, and platelet count 702,000. The urine dipstick showed 4+ proteinuria, with 5.5 gm of protein and 1.31 gm of creatinine in a 24-hour urine specimen. The serum creatinine level was 2.2 mg/dl, and the electrolyte values were sodium 125 mEq/L, potassium, 4 mEq/L; chloride, 100 mEq/L; carbon dioxide, 2-19 mEq/L. The blood glucose level was 75 mg/dl. The total protein was 3.8 mg/dl, serum albumin 0.9 mg/dl, and uric acid 6.2 mg/dl. An ultrasonographic examination of the kidneys showed normal-sized kidneys with no obstruction. Serologic studies for secondary causes of nephrotic syndrome, including hepatitis, syphilis, and lupus, were negative.

In view of the previous history of steroid-responsive nephrotic syndrome, a presumptive diagnosis of minimal-change nephropathy was made and the patient was started on 20 mg prednisone three times a day. Within a week of steroid therapy, the urine dipstick became negative, edema had decreased considerably, and serum creatinine levels had fallen to 0.6 mg/dl. Over the next 2 months the 24-hour urine excretion fell to 100 mg/24 hours and the prednisone was discontinued with no relapse. She was delivered of a 1960 gm boy at 35 weeks' gestation with Apgar scores of 9 at 1 and 5 minutes.

Comment

Renal failure during pregnancy presents an unusual challenge in diagnosis and management to the obstetrician. Whereas there are many causes of acute renal failure during pregnancy, the urinalysis provides the key in the evaluation of acute renal failure in the first two trimesters of pregnancy.[2] When this patient was first seen with edema, the urinalysis showed significant proteinuria, and a 24-hour urine collection confirmed the diagnosis of nephrotic syndrome. In general, the approach to patients with nephrotic syndrome depends heavily on the history and physical examination when trying to decide which patients have primary or

idiopathic forms of the nephrotic syndrome, or a secondary type associated with a systemic disease such as systemic lupus erythematosus, diabetes mellitus, or preeclampsia.

The history in this patient provided the key to the diagnosis. Because she was seen in early pregnancy without hypertension made preeclampsia unlikely, and there were no findings to suggest either diabetes or systemic lupus erythematosus. She had a clear history of steroid-responsive nephrotic syndrome beginning in childhood, typical of minimal-change nephropathy. Her history of explosive onset of severe nephrotic syndrome is also characteristic of this disorder. Acute renal failure is not typically associated with minimal-change nephropathy; however, this complication has been well described, particularly in adults with this disease. Although the diagnosis of this disease can be established with certainty only by renal biopsy, it was believed that the presentation was so typical of this disease that a therapeutic trial of corticosteroids was the safest approach. Rapid response to treatment with complete resolution of nephrotic syndrome and renal failure supported the diagnosis. If there had been no response to therapy, then a renal biopsy to exclude other disorders would have been appropriate.

This patient who was seen with renal failure in early pregnancy illustrates the importance of a systematic approach to this problem. By making a presumptive diagnosis of nephrotic syndrome as a result of minimal-change disease on the basis of her clinical presentation, therapy with prednisone led to an uneventful pregnancy with successful delivery.

Pharmacokinetics of acyclovir in the term human pregnancy and neonate

Lisa M. Frenkel, MD,[a] Zane A. Brown, MD,[b] Yvonne J. Bryson, MD,[a] Lawrence Corey, MD,[c] Jashvant D. Unadkat, PhD,[d] Paul A. Hensleigh, MD, PhD,[e] Ann M. Arvin, MD,[f] Charles G. Prober, MD,[f] and James D. Connor, MD[g]

Los Angeles, Stanford, and San Diego, California, and Seattle, Washington

Concern about neonatal herpes often leads to cesarean delivery of infants in women with a history of genital herpes. The antiviral drug acyclovir has been used effectively to suppress genital herpes simplex virus recurrences in nonpregnant adults. Its administration to pregnant women with recurrent genital herpes may reduce herpes simplex virus recurrences and thus may decrease the cesarean section rate among this population. To study the pharmacokinetics, safety, and patient tolerance of suppressive oral acyclovir, either 200 mg (n = 7) or 400 mg (n = 8) was administered orally every 8 hours to pregnant women with a history of recurrent herpes simplex virus, from 38 weeks' gestation until delivery. The mean ± SD plasma levels for the 200 and 400 mg groups, respectively, were: first dose peak, 1.7 ± 0.6 and 2.3 ± 1.0 μmol/L; steady-state trough, 0.7 ± 0.3 and 0.8 ± 0.6 μmol/L; steady-state peak, 1.9 ± 1.0 and 3.3 ± 1.0 μmol/L. In late gestation maternal acyclovir pharmacokinetics were similar to those of nonpregnant adults from other studies. Acyclovir was concentrated in the amniotic fluid; however, there was no accumulation in the fetus (mean maternal/infant plasma ratio at delivery was 1.3). Acyclovir was well tolerated, and no toxicity was seen in the mothers or infants. The administration of acyclovir, 400 mg every 8 hours, appears appropriate for use in an efficacy and safety study regarding suppression of herpes simplex virus recurrences during the last weeks of pregnancy. (Am J Obstet Gynecol 1991;164:569-76.)

Although neonatal herpes simplex virus (HSV) infections are not routinely reported to public health officials, studies from the state of Washington showed an increase in the incidence of neonatal herpes from 2.6 per 100,000 in 1969 to 11.9 per 100,000 in 1981[1] and to 15.4 per 100,000 from 1982 to 1985.[2] This increase probably occurred as the result of an increased prevalence of genital HSV infection in the population of childbearing age, as suggested by a nationwide 7.5-fold increase in private physician consultations for genital herpes from 1966 to 1981[3] and a similar increase in the incidence of genital herpes found in Rochester, Minnesota from 1965 to 1979.[4]

A cesarean section rate in excess of 50% has been reported for patients entering pregnancy with a history of symptomatic recurrent genital herpes, and is attributed in part to reactivation of HSV within 1 week of the onset of labor.[5] A substantial proportion (25%) of these cesarean sections has been assessed to be unnecessary[6] and to represent unwarranted risks, morbidity, and cost. In addition to the number of unnecessary cesarean deliveries, it is also disconcerting that cesarean section, even when performed before rupture of membranes, may not prevent transmission of HSV from the maternal birth canal to the infant.[7]

Acyclovir (Zovirax; Burroughs Wellcome, Research Triangle Park, N.C.), an antiviral agent, is activated selectively in HSV-infected cells and has been found to be safe and effective in the treatment of HSV infections, as well as in suppression of HSV recurrences in nonpregnant adults.[8-15] Acyclovir, taken orally in late pregnancy to supress reactivation of HSV, could reduce the high rate of cesarean section and the risk of HSV transmission to the infants of women with recurrent HSV infection. The appropriate dose and safety of acyclovir for use in human pregnancy have not been established. We studied the pharmacokinetics and safety of oral acyclovir in a group of pregnant women with recurrent genital HSV.

Study design and methods

Subjects were enrolled into this study at three medical centers: UCLA Medical Center in Los Angeles, the University of Washington in Seattle, and Stanford University Medical Center in Stanford, Calif. The protocol was approved by each institution's human subjects protection committee. After giving informed consent, subjects were given a screening interview and a physical examination. Only subjects with previous culture-documented genital HSV type 2 infection and a history of active recurrent genital lesions antedating and during pregnancy were included. Women with high-risk

pregnancies or active genital herpes lesions at the time of enrollment were excluded. Normal test results for complete blood count and differential cell count, serum creatinine, blood urea nitrogen, aspartate aminotransferase, alanine aminotransferase, bilirubin, and urinalysis were required for enrollment. Acyclovir was administered to 14 healthy women, beginning at 38 weeks' gestation until delivery, during 15 pregnancies. The first seven enrollees were given acyclovir at the dose recommended in the package insert for initiation of suppressive therapy (200 mg orally, every 8 hours).

Because acyclovir is erratically absorbed and because 200 mg acyclovir is not universally effective in suppressing clinical genital herpes, a subsequent group of eight subjects was studied at a dose of 400 mg administered every 8 hours. After the first dose of acyclovir, plasma of the patients was obtained to determine the peak value. Subjects were seen biweekly during the study period for cervical and vulvar HSV cultures and steady-state peak and trough acyclovir levels. In early labor the vulva and cervix were inspected and cultured for HSV. At delivery, maternal and cord blood were collected for determination of acyclovir concentrations, hematologic results, and blood chemistry values. In selected cases amniotic fluid, gastric aspirates of the infant, colostrum, and placental tissue were obtained for determination of acyclovir levels. The nasopharynx and rectum of the infants were cultured for HSV at birth and between 48 and 72 hours of life. If a fetal monitor was used, the site was also cultured. Maternal and infant blood samples were obtained in heparinized tubes at 1.5, 3, 6, 9, 12, 24, and 48 hours post partum for acyclovir determination of plasma levels. Acyclovir concentrations were determined by radioimmunoassay,[16] in the laboratory of James Connor, MD, at the University of California, San Diego. In addition to routine postpartum care, the well-being of the mothers and children at 6 months post partum was determined by physical examination and by telephone interviews with the patients or with their health care providers.

Results

Clinical and laboratory parameters of mothers and newborns (Table I). The mothers enrolled in our study were from 27 to 39 (mean, 31.7) years old, mostly (13/14) white, gravida 1 to 4 (mean, 2.1), para 0 to 1 (mean, 0.2), and had had recognized genital herpes for 1 to 10 years (mean, 4.4). During the pregnancies studied, these women had one to 10 (mean, 3.7) HSV recurrences. The acyclovir courses ranged between 3 and 29 (mean, 13.7) days' duration. Acyclovir was well tolerated by the mothers; there were no complaints of nausea, vomiting, headache, or other symptoms, and in all cases the complete blood count with differential cell count, alanine aminotransferase, aspartate aminotransferase, bilirubin, creatinine, blood urea nitrogen, and urinalysis (including no crystaluria) were normal on days 1, 6, and 11 or the last day of therapy). At birth, all infants appeared normal and were given Apgar scores ≥8. The cord blood and newborn complete blood count with differential cell count, alanine aminotransferase, aspartate aminotransferase, bilirubin, creatinine, blood urea nitrogen, and urinalysis values were normal. Except for a delay in the closure of the ductus arteriosus of one infant, there were no postnatal complications, and at 6 months of age all infants were reportedly normal.

Viral cultures and recurrences of genital HSV. No symptomatic HSV recurrences or asymptomatic viral shedding was noted in14 of the 15 pregnancies monitored during the study period. One woman (patient 2, who was taking 400 mg of acyclovir) entered the study

Table II. Peripartum acyclovir levels

	Acyclovir 200 mg t.i.d.

Placenta (μmol/L)	1.31	6.19	1.34	1.08	—	—	—
Breast milk (μmol/L)	—	—	—	—	—	—	—

Peripartum acyclovir levels for all subjects are shown (1 μmol/L = 0.225 μg/ml). Maternal acyclovir levels at time of birth were greater than those of infants (except for subject 6 of the 400 mg group), even though amniotic fluid levels were concentrated by a factor of 3 to 6. Breast milk samples were collected 4*(a)*, 3*(b)*, and 5*(c)* days after last acyclovir dose.

with a recently healed perianal HSV lesion. Culture on day 1 was negative for HSV. On the day after initiation of acyclovir (day 2), after two doses, HSV antigen was detected by an enzyme-linked immunosorbent assay on a specimen obtained from the site of the healed lesion. Labor began the next day, and the infant was delivered by cesarean section before rupture of membranes. Subsequently, a culture obtained on day 2 from the healed lesion site became positive for HSV. All cultures from this infant were negative for HSV, as were all the cultures from the other infants.

Acyclovir pharmacokinetics. Plasma acyclovir concentrations obtained after the first doses are shown in Fig. 1, *A*. The peak acyclovir plasma levels occurred between 1½ and 3 hours after the dose was administered. The mean ± SD acyclovir plasma levels at 1½ hours for the 200 and 400 mg dose groups were 1.7 ± 0.6 and 2.3 ± 1.0 μmol/L, respectively. One subject in the 200 mg dose group appeared to absorb acyclovir unusually well. In this patient acyclovir levels were evaluated by a statistical technique that tests extreme observations in a sample.[17] Her 1.5-hour value rose above the 95th percentile of the sampling distribution and therefore was excluded from the data analysis. The mean acyclovir plasma levels for the 200 and 400 mg doses, respectively, were 1.4 ± 1.3 and 2.4 ± 0.9, at 3 hours after the dose and 0.5 ± 0.1 and 1.0 ± 0.5 μmol/L at 6 hours after the dose.

Plasma acyclovir trough and peak concentrations obtained on days 6 and 11 were similar and are shown in a combined fashion in Fig. 1, *B*. The mean and SD plasma trough values of acyclovir in the 200 and 400 mg dose groups were 0.7 ± 0.3 and 0.8 ± 0.6 μmol/L, respectively. One subject in the 400 mg group took the drug three times daily instead of every 8 hours. This was reflected in high trough levels, which were determined 3 and 4 hours aftrer the previous dose. These values were excluded from the mean and SD calculation. During steady state, the 400 mg dose group's mean peak level (3.3 ± 1.0 μmol/L) was increased, as compared with the first-dose mean peak level (2.3 ± 1.1 μmol/L), whereas the suggestion of acyclovir accumulation was not seen during steady state in the 200 mg dose group with a steady-state mean acyclovir peak of 1.9 ± 1.0 μmol/L and a mean first-dose peak of 1.7 ± 0.6 μmol/L.

The peridelivery acyclovir levels are shown in Table II. The cord plasma acyclovir levels were less than the maternal acyclovir plasma levels that were obtained at the same time in all but one maternal-infant pair. In this latter case the mother's plasma acyclovir level of 0.7 μmol/L was low and was not significantly different from her infant's level of 0.8 μmol/L. The mean ratio of the maternal/cord acyclovir plasma levels was 1.3 ± 0.3. Acyclovir concentrations in the amniotic fluid (1.87 to 15.5 μmol/L, $n = 6$) were found to be three to six times higher than the corresponding cord plasma levels. Not surprisingly, gastric aspirates from the newborns ($n = 3$) had acyclovir levels similar to those of the amniotic fluid. At 3 to 5 days after the last dose of acyclovir was administered, low concentrations of the drug ($n = 2$) were detectable in breast milk. Also urine of the newborns that was collected between 12 hours and 3 days after the last dose of acyclovir had acyclovir levels between 7 and 140 μmol/L (data not shown).

The maternal plasma acyclovir levels obtained immediately before to 2 days after the last dose of acyclovir are shown in Fig. 2, together with the newborn

levels obtained from birth to 2 days after the last maternal dose of acyclovir. The values are plotted from the time since the last dose of acyclovir, not in relation to the time of parturition. The mean maternal (solid line) and newborn (dashed line) acyclovir plasma values are shown. The mean maternal acyclovir plasma level is higher than that obtained from the newborn shortly after the last dose of acyclovir. However, the maternal mean acyclovir level dropped more rapidly that that of the newborn, although maternal and infant levels were similarly low by 16 to 48 hours after the last dose of acyclovir.

Comment

This study shows that acyclovir, taken orally at doses of 600 to 1200 mg/day for 3 to 29 days, was well tolerated by women late in pregnancy and did not accumulate or cause adverse effects in their newborn infants. Pharmacokinetic values of acyclovir in the pregnant women studied were similar to values of nonpregnant adults, although these comparisons are made among a limited number of subjects. First-dose oral acyclovir peak values are not published for the 200 mg oral dose in nonpregnant humans; however, M.R. Blum, PhD, of Burroughs Wellcome, provided computer-simulated values for our dosage regimens from data compiled from trials conducted among nonpregnant subjects. The Burroughs Wellcome computer-projected plasma peak for a healthy adult who ingests 200 mg of acyclovir is 1.7 μmol/L, which is identical to our mean value of 1.7 ± 0.6 μmol/L. A first-dose mean acyclovir plasma peak in nonpregnant, healthy subjects who took 400 mg for a study of acyclovir suppression of recurrent genital herpes[15] was similar to that of our pregnant women and to the Burroughs Wellcome computed value (2.3 ± 0.4 vs 2.3 ± 1.0 vs 2.6, respectively). The pregnant women's steady-state acyclovir levels for the dose of 200 mg every 8 hours compared favorably with levels of nonpregnant adults[15] and with the Burroughs Wellcome computer-generated values (mean plasma trough levels of 0.7 ± 0.3 vs 0.7 ± 0.1 vs 0.4 μmol/L and peak levels of 1.9 ± 1.0 vs 2.0 ± 0.2 vs 2.0 μmol/L, respectively). No steady-state acyclovir values for 400 mg taken every 8 hours by nonpregnant humans have been published; however, our pregnant women's values were similar to the Burroughs Wellcome computed values with mean plasma trough values of 0.8 ± 0.6 versus 0.6 μmol/L and peak values of 3.3 ± 1.0 versus 3.0 μmol/L, respectively. The large standard deviations observed were not unexpected because acyclovir has a low bioavailability and is variably absorbed.[18]

The increased blood volume of pregnant women and hence the theoretical volume of distribution of acyclovir, coupled with an increased cardiac output and concomitant renal blood flow in late gestation, suggest that acyclovir levels may be less in pregnancy than in the nonpregnant state. Surprisingly, this was not observed among our population.

Acyclovir is excreted by glomerular filtration and tubular secretion.[18] The excretion of acyclovir by the pregnant women studied appeared normal and was demonstrated both by trough values similar to those of nonpregnant humans with normal renal function[15] and by the similarity in the day 6 and day 11 trough acyclovir values.

Acyclovir was concentrated in the amniotic fluid, presumably by excretion of acyclovir in the fetal urine. Approximately 85% to 95% of acyclovir is excreted unchanged in the urine.[19] The high levels of acyclovir in the amniotic fluid may provide a pharmacologic barrier for ascending or transamniotic membrane HSV infection. No accumulation of acyclovir was observed in the fetuses of the pregnant women studied. This is

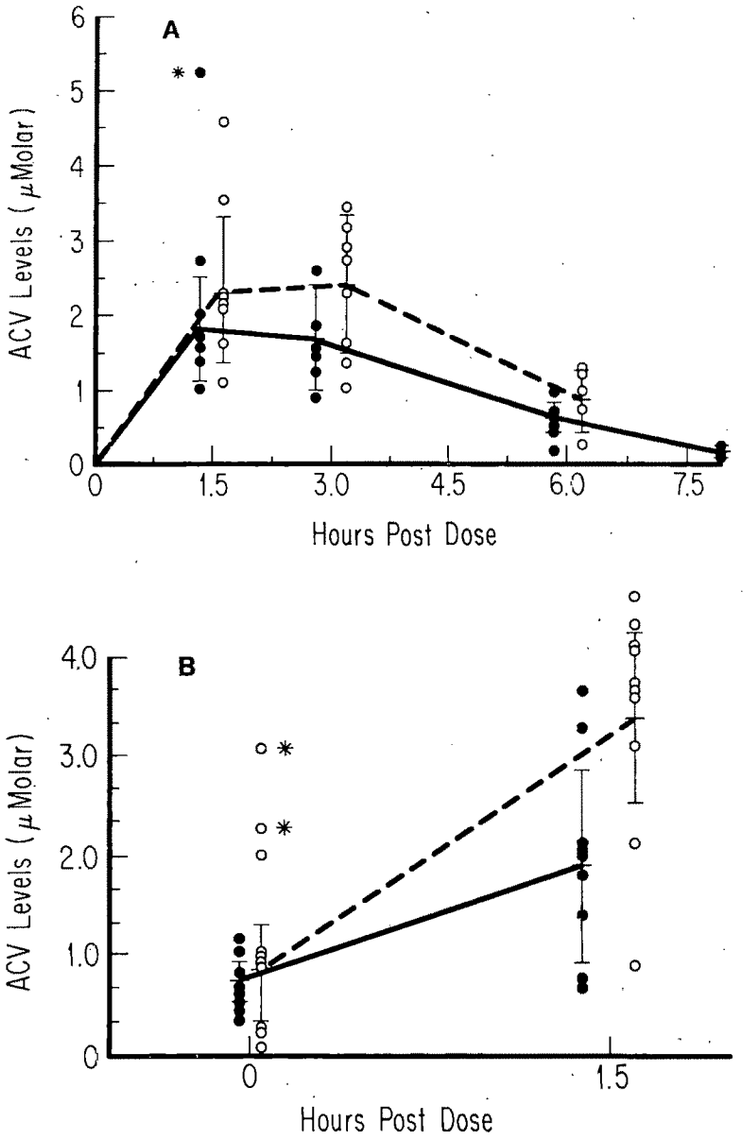

Fig. 1. Maternal acyclovir plasma levels on day 1 **(A)** and days 6 and 11 **(B).** Maternal acyclovir levels are shown as follows: **A,** first dose of 200 mg (●) and 400 mg (○). One subject *(asterisk)* absorbed the 200 mg dose of acyclovir unusually well for unclear reasons, her day 1, hour 1.5 value was above the 95th percentile of the sampling distribution for the group and therefore was excluded from the calculation of the mean and SD. Steady-state maternal acyclovir levels measured on day 6 and day 11 were similar, and are shown combined **(B).** One subject *(asterisk)* took 200 mg acyclovir three times daily instead of every 8 hours, and her elevated troughs are not included in the trough mean and SD. The 400 mg group's mean acyclovir steady-state peak of 3.3 ± 1.0 μmol/L shows accumulation of acyclovir, as compared with the day 1 mean peak of 2.3 ± 1.0 μmol/L, whereas the 200 mg day 1 and steady-state mean acyclovir plasma levels were similar, with values of 1.7 ± 0.6 and 1.9 ± 1.0 μmol/L, respectively.

an important observation, because very high acyclovir levels in the fetus could potentially cause an obstructive uropathy. A uropathy may occur when the acyclovir concentration in the renal tubules exceeds its solubility and crystallizes in the renal tubules and/or collecting ducts.[19] Glomerular filtration in the neonatal (and presumably in the fetal) kidney is impaired as compared with glomerular filtration in the adult kidney and is manifest in neonates by slower excretion of intravenous acyclovir as compared with excretion in adults.[20] Our data fail to demonstrate fetal accumulation of acyclovir, which suggests acyclovir equilibration across the pla-

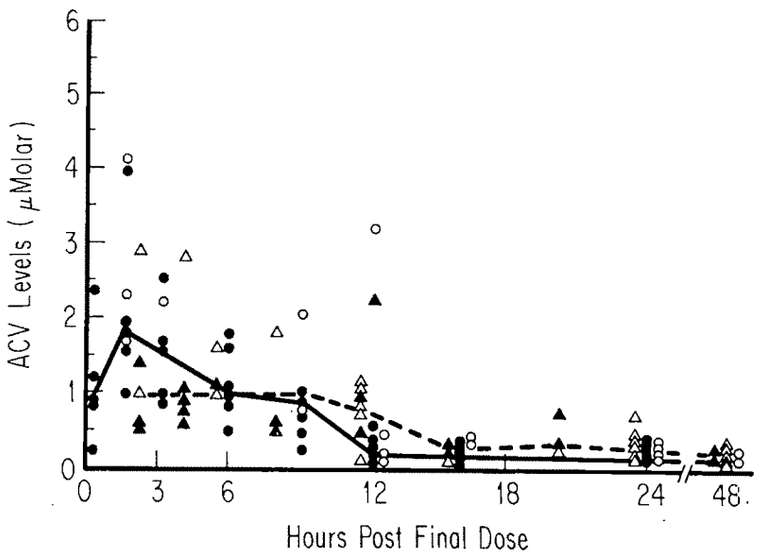

Fig. 2. Peripartum maternal and newborn acyclovir levels. Maternal and newborn plasma acyclovir levels are shown for 200 mg dose (●, mother; ▲, infant) and the 400 mg dose (○, mother; △, infant) as related to time since last maternal acyclovir dose. Delivery occurred at variable times after final acyclovir dose. *Lines* plot mean acyclovir plasma values for mother (——) and infant (- - - -) groups. Mothers had slightly higher plasma levels than did their infants soon after the last dose, but between 3 and 16 hours after the dose the mothers were noted to have excreted the acyclovir more rapidly than the newborns did.

centa. Within several hours of birth the decreased excretion of acyclovir by the neonatal kidney is observed, because the mean neonatal acyclovir plasma level exceeds that of the mothers (Fig. 2). However, by 16 hours after the last maternal acyclovir dose, both maternal and infant acyclovir levels are negligible.

Accumulation of acyclovir in breast milk has been reported.[21] Our breast milk data are sparse and do not examine peak acyclovir levels; however, as early as 2 days after acyclovir treatment is stopped, breast milk levels are negligible.

Of major concern is the safety of acyclovir treatment in the fetus. In animals, acyclovir has been studied in numerous toxicology, teratogenicity, and carcinogenicity studies.[22-27] The principal toxic effect is obstructive neuropathy, which generally ocurs with drug levels in excess of those used clinically.[24, 25] Mutagenicity has been seen in only three of more than 25 studies.[22, 25] No teratogenicity was seen in nine studies using three animal species that were given acyclovir in therapeutic doses (peak plasma levels, 1.1 to 8.6 μmol/L).[27] However, when acyclovir was given to pregnant rats in toxic doses (peak plasma levels, 440 ± 96 μmol/L) teratogenicity was observed, as was renal failure in the rat mothers.[26]

The exposure to acyclovir in this study began at 38 weeks' gestation. Since 1980 acyclovir has been given to neonates, including many premature infants, for treatment of herpes simplex infections. Thus far, no long-term effects have been identifed (Kirk E, MD, Burroughs Wellcome. Personal communication).

Burroughs Wellcome maintains a prospective registry of exposure to acyclovir in pregnancy, most of which took place during the first trimester.[28] Kenneth Lyons Jones, MD, at the University of California, San Diego, has a prospective registry of exposures to many substances, including acyclovir, during pregnancy. To date, these registries include follow-up of 112 pregnancies, and no increase or patterns of abnormalities have been observed as compared with pregnancies in which the fetuses were unexposed[26] (Jones K, MD, University of California, San Diego. Personal communication). The safety of acyclovir in early pregnancy is especially important with respect to its potential therapeutic use in the treatment of primary genital HSV infection during pregnancy, which may cause significant morbidity to both mother and infant.[29, 30]

The results of this study are reassuring, in that administration of acyclovir appeared safe for both mother and fetus when taken orally in late pregnancy. Especially noteworthy is the fact that acyclovir did not accumulate in the fetus at the doses used, in spite of its accumulation in the amniotic fluid. However, evaluation of the absolute safety of acyclovir in pregnancy will require a large, long-term, prospective, controlled (or case-controlled) study. Factors related to the morbidity of recurrent HSV infection in pregnancy are multiple and include not only infection of the infant but also an

increased rate of cesarean section with its risks and complications, the psychologic stress to the woman, and the difficulties in medical management associated with unpredictable, asymptomatic shedding of HSV from the cervix-vulva. Acyclovir treatment in the last part of pregnancy may positively affect these issues. However, a recent study of Straus et al.[31] suggests that asymptomatic shedding of genital herpes may not be decreased by suppressive acyclovir. Therefore we believe that a study to evaluate the safety and efficacy of oral acyclovir in suppressing recurrences and asymptomatic shedding of genital herpes in late gestation is warranted.

We thank Drs. M. Robert Blum and Edward Kirk of Burroughs Wellcome for contributing acyclovir pharmacokinetic and toxicology data; Dr. Kenneth Jones at the University of California, San Diego, for data from his registry of drug ingestion during pregnancy; Ms. Maryanne Dillon, Ms. Sylvia Berry, Dr. Richard Frieder and Dr. Yvonne Fried for their clinical assistance, and Dr. Louise Schumann for statistical work.

Ovarian neoplasms and the risk of adnexal torsion

Marianne Sommerville, MD, David A. Grimes, MD, Paul P. Koonings, MD, and Keith Campbell, MD
Los Angeles, California

Previous reports examining adnexal torsion suggested that benign ovarian neoplasms are more likely to undergo torsion than malignant ovarian neoplasms. To our knowledge, this clinical observation has not been quantified. To examine this hypothesis, we reviewed our experience with ovarian neoplasms found at the time of surgery over a 10-year period. Benign ovarian neoplasms had a 12.9-fold increased risk of undergoing adnexal torsion when compared with malignant ovarian neoplasms (95% confidence interval, 10.2 to 15.9). The histologic type of ovarian neoplasm does not appear to affect the rate of adnexal torsion. Adnexal torsion rarely involves cancer. (AM J OBSTET GYNECOL 1991;164:577-8.)

Key words: Torsion, ovarian neoplasms

The most common antecedent of adnexal torsion is a benign ovarian neoplasm.[1, 2] However, previous reports have not determined whether this apparent propensity of benign ovarian neoplasms to undergo adnexal torsion is due to their greater frequency, as compared with malignant ovarian neoplasms, or to a higher risk of torsion. To address this question, we reviewed our experience with adnexal torsion involving ovarian neoplasms.

Material and methods

The hospital records of 861 patients undergoing laparotomy at Women's Hospital, Los Angeles County–University of Southern California Medical Center from July 1, 1975, to June 30, 1985, with a pathologic diagnosis of ovarian neoplasm were reviewed. These methods have been described previously.[3] Tuboovarian abscesses, nonneoplastic cysts, paratubal cysts, and metastases from other organs were excluded. Calculation of the frequency of various types of ovarian neoplasms was performed with regard to both malignant potential and histologic type. Torsion was defined as a minimum of 360 degrees rotation of the adnexum. Rates and relative risks with 95% confidence intervals were calculated.

Results

Adnexal torsion was identified in 98 patients with an ovarian neoplasm (11%). Ninety-three patients with adnexal torsion had benign ovarian neoplasms (95%), three had neoplasms of low malignant potential (3%), and two had malignant ovarian neoplasms (2%).

The risk of torsion in premenopausal women did not differ from that in postmenopausal women, when controlled for malignancy. Moreover, parity did not appear to affect the risk of an ovarian neoplasm undergoing torsion (data not shown).

Benign ovarian neoplasms had a 12.9-fold increased risk ($p < 0.001$) of being involved in adnexal torsion, as compared with malignant ovarian neoplasms (Table I). Neoplasms of low malignant potential had an 8.7-fold increased risk of torsion as compared with malignant ovarian neoplasms, although this was not statistically significant.

Among the benign ovarian neoplasms that underwent adnexal torsion, no single tumor type appeared to have a predilection for undergoing torsion (data not shown). This was true for neoplasms of low malignant potential and malignant ovarian neoplasms. The rates of torsion were 9.5 per 100 women with neoplasms of epithelial origin, 13.6 for germ cell neoplasms, and 10.5 for stromal neoplasms ($p > 0.05$).

Comment

The clinical impression that malignant ovarian neoplasms are less likely than benign ovarian neoplasms to undergo adnexal torsion has been reported previously.[1, 2] Because malignant ovarian neoplasms are less common than benign ovarian neoplasms, this discrepancy in relative frequency could account for this difference.[3] Alternatively, this low probability of malignant ovarian neoplasms undergoing torsion may be explained by their ability to adhere to local structures. This may be caused by inflammation, adhesions, or local invasion.

Table I. Rates and relative risks of adnexal torsion by malignant potential of ovarian neoplasm

	No. of patients with ovarian neoplasms undergoing torsion	*Total no. of patients with ovarian neoplasms*	*Rate**	*Relative risk†*	*95% Confidence interval*
Benign	93	650	14.3	12.9	10.2-15.9
Borderline	3	31	9.7	8.7	1.0-24.8
Malignant	2	180	1.1	1.0	Referent
TOTAL	98	861	—	—	—

*Per 100 patients.
†On the basis of an index rate of 1.1 for malignant neoplasms.

Earlier descriptions of ovarian neoplasms have been limited in scope and have not usually provided rates of torsion by tumor type.[2] Although Hibbard[1] did not use statistical tests, he compared rates of torsion by tumor type. Our study confirms that malignant ovarian neoplasms are less likely to undergo adnexal torsion than benign ovarian neoplasms. Whether this is also true for neoplasms of low malignant potential is not clear because of limited numbers of such case.

In summary, ovarian neoplasms that undergo adnexal torsion are usually benign. These findings should be helpful to the surgeon in choosing the operative approach in surgical emergencies and in patients in whom more thorough preoperative evaluation may be impossible.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Laparoscopic pelvic lymphadenectomy in the staging of early carcinoma of the cervix

Denis Querleu, MD,[a] Eric Leblanc, MD,[b] and Bernard Castelain, MD[c]
Roubaix and Lille, France

Laparoscopic pelvic lymphadenectomy was performed in 39 patients. An incision of the peritoneum between the round and infundibulo-pelvic ligament on each side gave access to the retroperitoneal space. Subsequently, laparoscopic surgery allowed precise dissection of external and internal iliac vessels, umbilical artery, and obturator nerve. The peritoneum was left open, and the lymph was drained into the peritoneal cavity. No lymphocele was observed. Three to 22 (mean, 8.7) nodes were removed, and there was no significant morbidity. Sensitivity and specificity were 100% in this preliminary experience. It is thus possible to remove the first-line regional lymph nodes of the cervix for pathologic examination. Because "skip" metastases are quite rare in early cervical carcinoma, the risk of missing a positive node is low. Brachytherapy alone, vaginal surgery, or, in microinvasive carcinoma, conization alone can be applied safely without the need of a staging laparotomy in cases with negative nodes. (AM J OBSTET GYNECOL 1991;164:579-31.)

Key words: Laparoscopic surgery, carcinoma of the cervix, pelvic lymphadenectomy

The presence of lymph node metastasis is the most significant prognostic factor in carcinoma of the cervix, particularly in those patients with early stage tumors. The management of a patient with invasive carcinoma of the uterine cervix is based on the results of both the clinical examination and diagnostic imaging. Furthermore, pathologic examination identifies those patients with International Federation of Gynecology and Obstetrics (FIGO) stage IA cervical carcinoma in whom there is a risk of lymph-node metastases.

Current clinical staging methods are inaccurate in the detection of metastases to the pelvic lymph nodes. The sensitivity of lymphangiography is less than 30%.[1] This technique does not allow the visualization of internal iliac and other medial node groups. Computed tomographic scanning and magnetic resonance imaging are quite insensitive if the nodes are not macroscopically enlarged.[1-3] Finally, lymphoscintigraphy is too unreliable for routine use.[4]

Lymph node biopsy is thus the only reliable method to appraise the status of pelvic lymph nodes. However, the pathologic specimens are taken either during a presurgical staging laparotomy, which adds significant morbidity, or during the surgical step of treatment, at a time when primary decisions have already been made. Attempts at pelvic lymph node removal by a retroperitoneal endoscopic approach have previously been described.[5,6] Progress in laparoscopic surgery provides the opportunity to remove the primary regional lymph nodes with minimal surgical trauma. We describe in this paper the surgical technique of obturator, external iliac, and hypogastric lymphadenectomy with the use of the laparoscope.

From the Clinique Universitaire de Gynécologie-Obstétrique, Pavillon Paul Gellé, Roubaix,[a] and the Département de Chirurgie[b] and the Département de Radiothérapie,[c] Centre Oscar Lambret, Lille.

6/1/25058

Patients and methods

The surgical technique is essentially the same in every case. No uterine cannulation is necessary, and the patient is placed in the supine position without any flexion of the hips. While the patient is under general anesthesia with tracheal intubation, a pneumoperitoneum is created and an 11 mm laparoscope (Karl Storz, Germany) is inserted through a minimal umbilical incision. A video camera is installed. After observation of the liver surface, the appendix, and the internal genitalia, two 5 mm incisions are made in the right and left inguinal areas, and trocars are inserted into the abdomen. Ancillary 4.5 mm scissors, prehensile forceps, and irrigation-aspiration devices (Micro-France, Bourbon-l'Archambault, France) are consequently available throughout the procedure. An additional opening is made in the midline above the symphysis pubis, and an 8 mm trocar is placed so that the surgeon is ready at any time to use endoscopic clips (Ethicon, Paris) and later to remove lymph nodes from the abdomen with a three-arm retractable Dargent forceps (Lépine, Lyon).

Pelvic lymphadenectomy is performed on each side as follows. External iliac vessels and umbilical artery are identified under the peritoneal surface. The operation begins with an incision of the pelvic peritoneum be-

tween the round and infundibulopelvic ligaments, parallel to the axis of the external iliac vessels. The round ligament is grasped with a forceps, and the peritoneum is cut, then easily torn to open the whole area between the round and infundibulopelvic ligaments. The paracystic space is opened and then widened by blunt dissection between the umbilical artery medially and the external iliac vessels laterally. The pelvic floor is easily reached without any bleeding. The instrument that grasps the round ligament is freed, closed, placed in the paravesical space, and retracts the umbilical artery medially. The cellulolymphatic area below the external iliac vein is then clearly visible and safely dissected. The obturator nerve is identified and dissected caudally to the point at which it leaves the pelvis. The inferior aspect of the external iliac vein is separated by blunt dissection with a closed forceps. The fatty tissue between the obturator nerve and the external iliac vein is then grasped and thoroughly separated from the pelvic wall. At this point, the pelvic bone and the internal obturator muscle are exposed. Care must be taken to avoid injury to retropubic veins and the venous anastomosis between obturator and external iliac veins. However, the magnification that is provided by the laparoscope placed at a short distance from the surgical field allows precise dissection of the vessels, and such an injury has never occurred in our experience. The caudal part of the connective tissue pedicle is then detached from the area of the obturator foramen and of the femoral canal. It is separated by gentle traction. Bleeding is quite unusual at this step, perhaps as a consequence of pressure that is induced by the pneumoperitoneum. The tissue flap is then firmly grasped and moved cranially; it is carefully dissected from the external iliac vein and artery laterally and from the umbilical artery medially. At this point, the cellulolymphatic flap is only attached in the interiliac bifurcation area. It is gently separated by traction and blunt dissection. The tissue sample must then be extracted from the abdomen by means of the Dargent forceps (Lepine). This instrument allows easy removal of the lymph nodes without any risk of contamination of the abdominal wall by tumoral cells, but the specimen may have to be divided into two or three parts. The same technique is carried out on the opposite side. When large adherent pelvic metastases are seen, needle aspiration may replace removal of the node. Hemostasis is then checked. A minimal amount of blood may have to be aspirated. At the end of the procedure, the peritoneum is left open to allow drainage of the lymphatic fluid into the abdomen. In premenopausal patients with mobile ovaries, when brachytherapy is planned, a laparoscopic transposition of the ovaries to the abdominal wall may be performed to avoid ovarian irradiation.

Thirty-nine patients who presented with FIGO stages IB (n = 9), IIA (n = 7), and proximal IIB (n = 13) carcinoma of the cervix underwent pretreatment laparoscopic staging between December 1988 and December 1989. Selection of patients was based on the potential risks of prolonged pneumoperitoneum and the absence of cytologically positive nodes that were visible on computed tomographic scans. Their age range was 28 to 69 years, including 15 patients older than age 50. The pathologic types of the cervical tumors were squamous carcinoma (n = 35) or adenocarcinoma (n = 4). The primary regional lymph nodes were histologically examined by frozen sections and/or pathologically examined in all but two cases. In these last two cases, metastatic epithelial cells were demonstrated on needle aspirates of unresectable nodes.

Five patients with metastatic nodes were given the option of radiation therapy alone. All other patients were operated on later (the same day or 1 to 6 weeks later). Two patients underwent Schauta-Amreich radical vaginal hysterectomy. The last 32 patients had Wertheim abdominal radical hysterectomy with pathologic control of occasional remaining primary and of palpable secondary primitive iliac or paraaortic lymph nodes.

Results

One to 15 nodes were removed from each side (mean, 4.2 on the right and 4.9 on the left side). As a whole, 3 to 22 nodes were available for pathologic examination (mean, 8.7). No unexpected metastatic node was observed at laparotomy in 32 cases. Finally, sensitivity and specificity were 100% in this series.

The procedure typically lasted 90 minutes. Two intraoperative complications were observed. One patient did not tolerate the prolonged pneumoperitoneum, and we had to abandon the procedure after removal of only three nodes. In another case, bleeding from the umbilical artery necessitated bipolar coagulation of the vessel. No unwanted laparotomy was necessary. Clips were never used, and minimal bleedings occurred under irrigation with warm saline solution. The postoperative period was uneventful, and patients were discharged from the surgical ward on the following day in all but one case. In this case, a spontaneously resolutive pelvic hematoma was observed 5 days after laparoscopic pelvic lymphadenectomy and radium application. No lymphocele was observed. No bowel adhesions were noticed at further laparotomy, and spontaneous healing of the peritoneum always occurred without intraperitoneal sequelae. However, dense fibrosis of the retroperitoneal tissue was noticed in some cases.

Comment

Pathologic examination is the gold standard in the detection of lymph node metastasis. Pretreatment surgical staging provides the most sensitive means of di-

agnosing node involvement. However, the cost and risks of open-field pretherapeutic surgical staging preclude its general application in clinical practice, particularly in early stage carcinoma of the cervix, in which the prevalence of node metastasis is rather low. Progress in endoscopic surgery should dramatically reduce the cost of pathologic staging of pelvic nodes.

However, laparoscopy, as well as surgical staging, is useless if suspicious lymph nodes shown by computed tomographic scanning have been proved positive by percutaneous fine-needle aspiration. Furthermore, it is at this time impossible to explore paraaortic nodes by laparoscopy. A retroperitoneal approach is preferable in the paraaortic area.[5] It could be used in patients at risk of secondary lymph node metastasis, that is, in patients with locally advanced tumors or early stage cervical cancers with positive pelvic nodes. However, the poor outcome of patients with paraaortic nodal metastasis, regardless of treatment, does not seem to justify the risks of paraaortic staging for all patients in a noninvestigational setting.

The accuracy of a negative laparoscopic lymphadenectomy is excellent. Sensitivity is 100% in this series. The risk of "skip" metastases (primitive iliac or paraaortic nodes without pelvic node involvement) is very low in cases of early stage invasive cervical cancer (<2%)[6] and seems to occur only in patients with large tumoral volume.

As a consequence, FIGO stage I, IIA, or proximal IIB cases with negative pathologic staging may be cured by vaginal surgery alone or by brachytherapy alone without the need for external radiotherapy. On the other hand, radical hysterectomy does not seem necessary when metastatic nodes are present.[7] The consequent reduction of risks and cost justifies the additional general anesthesia and the short hospital stay of a diagnostic laparoscopy. At this time, our treatment protocol for early stage "operable" cervical carcinoma includes laparoscopic lymphadenectomy. Patients with positive nodes are given the option of radiotherapy alone. Patients with negative nodes have had brachytherapy and then abdominal surgery during the first step of the investigation; since the accuracy of staging laparoscopy has been proved, we suggest only radical vaginal surgery or brachytherapy.

Some FIGO stage IA2 cervical carcinomas without pelvic node metastasis can be treated by cervical conization alone. When hysterectomy is not necessary for the local control of such tumors, laparoscopic lymphadenectomy helps to identify women of reproductive age with microinvasive carcinomas who may benefit from conservative therapy. The rare cases with node metastasis, which justify a radical treatment protocol, can be differentiated from cases with negative nodes in which cervical conization with preservation of fertility is an acceptable treatment.

Laparoscopic lymphadenectomy is a feasible alternative to laparotomy for lymph node staging of carcinoma of the cervix. It helps to reduce the cost, risks, and effects on fertility in the majority of cases of early stage cervical carcinoma. Its risks seem to be low, since no serious surgical complication has been observed in this series. In particular, the absence of lymphoceles is a consequence of the intraperitoneal lymph drainage during the postoperative period before spontaneous peritoneal healing has occurred. However, it should be stressed that prolonged pneumoperitoneum may be contraindicated in patients with cardiac or pulmonary diseases or in obese patients. Moreover, this technique should be used only by surgeons who work in referral centers and who have considerable expertise in gynecologic-oncologic surgery and in surgical laparoscopy.

Umbilical cord ulceration and intestinal atresia: A new association?

Robert W. Bendon, MD[a], R. Wes Tyson, MD,[b, c] Virginia J. Baldwin, MD,[b, c]
Kathryn A. Cashner, MD,[d] Francis Mimouni, MD,[e] and Menachem Miodovnik, MD[d]
Cincinnati, Ohio, and Vancouver, British Columbia, Canada

In three fetuses, congenital intestinal atresia was associated with linear ulcerations of the umbilical cord. In two cases, hemorrhage was seen from the cord ulcer. Both fetuses required emergency cesarean section for fetal distress and were born anemic. The third fetus was mildly hydropic, attributed to hemorrhage, and was stillborn. The mechanism of the association could not be determined. These cases suggest a risk of prenatal umbilical cord hemorrhage in infants with intestinal atresia. (Am J Obstet Gynecol 1991;164: 582-6.)

Key words: Intestinal atresia, umbilical cord, fetal hemorrhage, ulceration

Massive hemorrhage from the umbilical cord has been reported to occur with some rare lesions such as hemangiomas.[1] Bleeding from ulceration of the cord has seldom been reported.[2] We report three cases with suspected in utero hemorrhage from umbilical cord ulcerations. All three fetuses also had congenital intestinal atresia.

Clinical histories

Case 1. The mother was a 19-year-old, gravida 3 woman with two previous term pregnancies. She smoked cigarettes and took aminophylline for the treatment of asthma.

At 31 weeks' gestation by dates, she was seen in preterm labor with advanced dilatation. Examination suggested polyhydramnios (41 cm fundal height), which was confirmed by ultrasonographic examination.

Artificial rupture of membranes released copious bloody amniotic fluid. Late fetal heart rate (FHR) decelerations developed, followed by an abrupt fall to 50 beats/min. A 1830 gm male infant was delivered by emergency cesarean section. Apgar scores were 1, 3, and 7 at 1, 5, and 10 minutes, respectively. The operative note reported "many small black tags (clots)" along the length of the umbilical cord.

The infant was pale at birth and his initial hematocrit value was 28%. A transfusion of 20 ml of packed red blood cells per kilogram body weight raised the hematocrit value to 53%. The infant was appropriate for gestational age of 31 weeks. A chest radiograph showed mild respiratory distress syndrome and the "double-bubble" sign of duodenal atresia. At 6 days of age, he underwent duodenostomy and gastrostomy for an atresia in the second part of the duodenum. He did well postoperatively and was discharged 40 days later.

He was treated for asthma as an infant. At 4 years of age, he still has asthma and persistent vomiting.

Case 2. The mother was a 27-year-old gravida 2 woman with a previous uncomplicated term pregnancy. Her medical and social history were unremarkable. She was seen at 34 weeks' gestation because of spontaneous rupture of membranes. An ultrasonographic examination after rupture of membranes showed a normal volume of amniotic fluid (suggesting previous polyhydramnios), an immature placenta, and a fetus with aortic stenosis and bowel atresia. The baseline FHR was 100 to 110 beats/min with normal variability on an external monitor.

Four days later, an amniocentesis was performed for maturity studies. The fluid was bloody and unanalyzable. The FHR was monitored and remained reactive with a slow baseline. Eleven hours later a fetal bradycardia in the 60s was sustained for 9 minutes. An emergency cesarean section was performed. A 2020 gm male infant was delivered with Apgar scores of 3 at 1 minute, 4 at 5 minutes, and 6 at 10 minutes. The cord blood had a pH of 7.24 and a base deficit of 6.6. The amniotic fluid was bloody.

The infant was appropriate for a gestational age of 34 weeks, and the birth weight was 2020 gm (70th percentile). Heart rate was 98, respiratory rate was 50, and blood pressure was undetectable. The precordium was hyperactive. The pulses and capillary refill were decreased. An umbilical cord clamp had been placed in

the delivery room approximately 2 cm above the abdomen. A 4 to 5 cm stump of umbilical cord remained above the clamp. This portion showed a 2 cm linear ulcer, 2 to 4 mm wide, that exposed one umbilical artery. The vessel appeared necrotic with an adherent blood clot. The hematocrit value was below detection. The infant was resuscitated with 70 ml of packed red blood cells and 20 ml of plasmanate human plasma protein fraction with intravenous dopamine at 10 μg/kg per minute. At 30 minutes after birth his blood pressure was 36/16 with a mean arterial pressure of 29.

On day 9 after birth, he underwent exploratory laparotomy, at which time multiple atretic areas of the distal jejunum were found and resected. Echocardiography showed mild to moderate tricuspid insufficiency, enlarged right ventricle, small perimembranous ventricular septal defect, a borderline small aortic root, and abnormal motion of the posterior mitral leaflet. The infant was discharged from the Neonatal Intensive Care Unit and is followed up by cardiologists.

Case 3. The mother was a 21-year-old primigravid woman. Her pregnancy was complicated in the first trimester by bronchitis treated with penicillin, and in the last month by a 15-pound weight gain and increasing abdominal girth. She smoked 10 to 15 cigarettes per day.

At an estimated gestation of 30 weeks, she was admitted to the hospital in preterm labor, but labor did not progress. On the last evening, a FHR tracing showed a rate of 170 to 180 beats/min. Four hours later, a heart beat could not be detected and an ultrasonographic examination confirmed fetal death. Artificial rupture of membranes produced clear fluid for 15 minutes and then bloody fluid and a 3 to 4 cm blood clot. A 1700 gm, stillborn female fetus was delivered vaginally. Autopsy revealed development consistent with 30 weeks' gestation, preampullary duodenal atresia, and linear umbilical cord ulcerations.

Pathologic findings

Case 1. The fixed placenta was normal in weight, dimension, and gross examination. Ten centimeters of umbilical cord were attached and another 7 cm were received separately. The cord was stained brown. Gross ulcerations with small adherent clots followed the spiral of one dilated umbilical artery (Fig. 1, *A*). Sections of the placenta, umbilical cord, and roll of fetal membranes were processed for histologic examination. Stains performed on the umbilical cord included hematoxylin-eosin, Prussian blue, alcian blue–PAS, Grocott-Gomori methenamine-silver nitrate, Giemsa, Gram, acid fast, elastin, and immunoperoxidase localization of cytokeratin.[3]

Histologically, the umbilical ulcer bed was filled with amorphous debris, red blood cells, squames, and plump, often multinucleate or clumped, epithelial cells (cytokeratin-positive) (Fig. 2, *A*). The ulcer bed was superficial to and between the arteries. No organisms were detected. There was acute inflammation of the umbilical vein but not of the arteries. Placental findings also included mild acute inflammation of the intervillous, subchorionic fibrin, mildly hydropic villi, and Prussian blue–negative, pigment laden macrophages in the amnion and chorion.

Case 2. The drained, trimmed weight of the fresh placenta was 380 gm. The umbilical cord was 22 cm long and inserted centrally. The cord had a tight spiral with a depression along the inner groove showing focal ulceration (Fig. 1, *B*). The fetal membranes had a light grey-green discoloration. The serial cut surfaces of the placenta were pale. Sections of the umbilical cord, membranes, and placenta were studied histologically and stained with hematoxylin-eosin and Prussian blue for iron.

Microscopically, the ulcer ran between the two umbilical arteries. The ulcer had the same histologic characteristics as case 1 (Fig. 2, *B*). One artery was markedly dilated, but not necrotic. Acute inflammation was not evident in either the umbilical cord or the membranes. There were plentiful pigment-filled macrophages in the fetal membranes. The pigment did not stain for iron. The placental villi were mildly hydropic.

Case 3. The trimmed placenta weighed 375 gm and appeared meconium-stained. The three-vessel umbilical cord was received in two pieces, 16 and 25 cm long, respectively. There were two linear ulcers following the course of the umbilical vessels (Fig. 1, *C*). The cord had a brown discoloration. The maternal surface of the placenta had an ill-defined area of compression and a 10 cm adherent marginal thrombus. The cut sections of the placenta were pale.

Microscopically, the ulcer bed had the same histologic characteristics as cases 1 and 2, but in addition focally overlaid the vein (Fig. 2, *C*). There was mild acute vasculitis of the arteries and vein without necrosis of the vessel wall. The fetal membranes contained rare neutrophils and meconium pigment contained within macrophages. There was focal, mild nonspecific villitis.

At autopsy the 1700 gm female fetus was estimated to be 32 weeks' gestation with early maceration. There was mild hydrops with periorbital edema, 10 ml of fluid in the pleural spaces, 2.5 ml pericardial effusion, and 3 ml of ascites. There was a preampullary membranous duodenal atresia with a moderately dilated stomach. Evidence of acute fetal distress included intrathoracic petechiae and sufficient amniotic debris to suggest aspiration. Chromosome analysis revealed a normal 46,XY karyotype.

Comment

These three cases had similar pathologic conditions (an ulceration of the umbilical cord), congenital intestinal atresia, and probable in utero hemorrhage. Three tentative conclusions can be drawn from the case findings. First, the pathologic findings provide constraints on the possible mechanism of ulcer formation. Second, clinically severe hemorrhage from the ulcers occurred in utero in at least two cases. Third, the ulcers were associated with fetal intestinal atresia but no mechanism can be determined, as yet, from the clinical or pathologic observations.

The three cases shared the following anatomic findings. Grossly, the ulcers paralleled the vascular helix. They were superficial to the arteries and in one case to the vein. The ulcer beds contained necrotic debris but little inflammation. No organisms were found with special stains; no viral inclusions were identified. Large, sometimes multinucleated, cells in the ulcer bed were epithelial.

The ulcers could have been linear for one of two reasons. Possibly, the epithelial surface was more susceptible to injury in a linear pattern related to the underlying vessels because of varying oxygenation or the effects of mechanical pulsation. Alternatively, an injurious substance dissected along channels of least resistance in the nonhomogeneous Wharton's jelly with epithelial ulceration occurring as a result. However, the initiating injury or injurious substance remains undetermined.

The hemorrhages into the amnionic cavity appear to have been from the exposed umbilical vessels. In the first case, adherent clotted blood was seen on the umbilical cord at cesarean section by the obstetrician. Necrosis of the umbilical artery was confirmed microscopically. In the second case, hemorrhage from the attached cord segment was seen by the neonatologist. Both infants were anemic at birth. The third fetus was hydropic, which can occur after fetal hemorrhage.[4] No other cause of hydrops was detected. Fetal hemorrhage could have occurred from the umbilical cord ulcer, although no specific site was found.

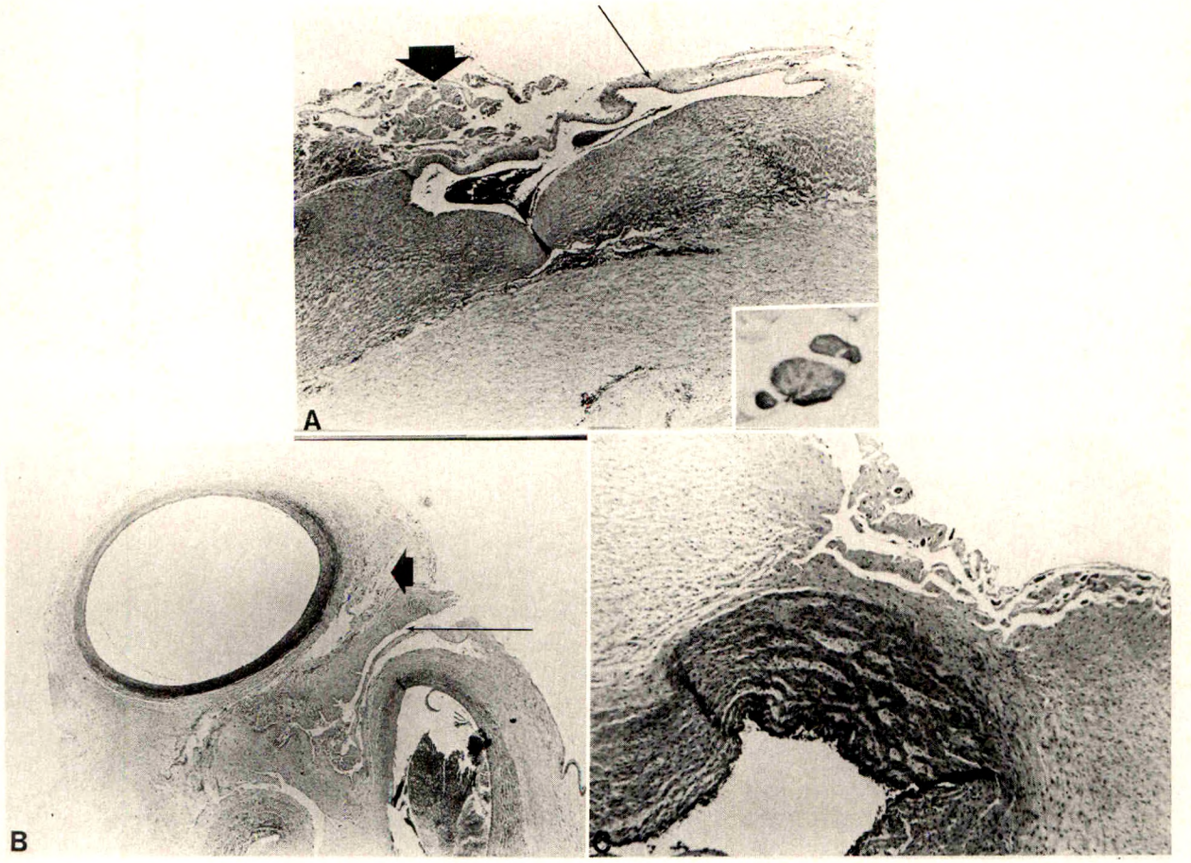

Fig. 2, A. Case 1, *arrow* points to thinned, superficial wall of umbilical artery that has been exposed by ulcer. *Arrowhead* points to ulcer bed debris with large epithelial cells. (Hematoxylin-eosin stain; ×33.) *Inset*, Anticytokeratin positivity of large epithelial cells. (Hematoxylin counterstain; ×250.) **B,** Case 2, ulcer bed *(arrowhead)* is alongside deep, nonpathologic, groove between arteries *(arrow)*. (Hematoxylin-eosin stain; ×25.) **C,** Case 3, ulcer overlies umbilical vein, which also shows some acute inflammation of vessel wall. Ulcer bed shows large epithelial cells. (Hematoxylin-eosin stain; ×12.5.)

We considered three general hypotheses to account for the association of umbilical cord ulceration with intestinal atresia: vascular reactivity, gastric reflux, and epithelial abnormalities. In the first hypothesis, an abnormal vascular reactivity could produce both lesions. Experimental and clinical evidence suport an ischemic origin of congenital intestinal atresia,[5] and the umbilical cord arteries have the capacity to maintain a prolonged vascular spasm after delivery.[6] If such a spasm was initiated in one artery in utero it might cause an ischemic ulcer of the umbilical cord. In two cases, the mothers smoked cigarettes, a potential source of vasoconstrictor; one of these mothers and her infant have asthma, possible evidence of abnormal smooth muscle reactivity. In the second hypothesis, the intestinal atresia might produce reflux of gastric or duodenal contents that could initiate an ulcer. The hemosiderin-negative, green-brown pigment in the amniotic and chorionic macrophages may reflect phagocytosis of bilious reflux. This hypothesis is supported by the observation of increased optical density of the amnion fluid at 450 nm in a case of duodenal atresia.[7] In the third hypothesis, a primary epithelial abnormality might produce both intestinal atresia and the cord ulcer similar to the association of epidermolysis bullosa with intestinal atresia.[8] However, our findings could not prove or disprove any of these hypotheses.

Review of the English literature found no identical cases. Cords with absence of Wharton's jelly have a superficial resemblance to our umbilical cord ulcers, but are pathologically and clinically different.[9,10] A morphologically very similar ulcer that produced lethal prenatal hemorrhage was reported in association with an omphalomesenteric duct extending from the ileum.[2] Within the umbilical cord, the duct was lined with gastric mucosa, analogous to some Meckel's diverticula.

Microscopy showed that the duct was the source of the ulcer. Another related case with severe in utero hemorrhage and distal ileal atresia was attributed to an umbilical cord hemangioma.[11]

The association of congenital intestinal atresia and umbilical cord ulceration and hemorrhage may be clinically important. The delay in recognition of the potential for hemorrhage probably contributed to the morbidity and mortality in our cases. If the risk of hemorrhage is recognized in prenatally diagnosed congenital bowel atresia, this may permit delivery before severe blood loss has occurred. Although present in only two of our three cases, a short umbilical cord may be an additional indicator of risk. In two of our cases, the umbilical ulcer was not recognized clinically even after delivery. This suggests that the lesion may occur more frequently than the literature review would indicate.

We thank Jay Card for photographic assistance and Dr. Keith Williams, Department of Obstetrics, University of British Columbia, for use of his case (case 3).

Mechanisms of hemolysis and anemia associated with acute antepartum pyelonephritis

Susan M. Cox, MD, Paul Shelburne, MD, Ruble Mason, MT, ASCP, Stephen Guss, MS, and F. Gary Cunningham, MD

Dallas, Texas

Anemia develops in about a fourth of women whose pregnancy is complicated by pyelonephritis, although its exact mechanism has not been defined clearly. In this study of 18 women with antepartum pyelonephritis, although only a third had anemia (hematocrit <30 vol/dl), there was evidence for hemolysis in all 18. Specifically there was a mean decrease in hematocrit of 5 vol/dl from admission to discharge. With scanning electron microscopy, we compared erythrocyte morphologic aberrations that were found in women with renal infection with those of normally pregnant women, and the former had significantly increased proportions of echinocytes in particular, but schistocytes and spherocytes were increased also (total 10.3% vs 1.4%, $p < 0.0001$). These changes, especially echinocytosis, have been induced in vitro by lipopolysaccharide, and they are known to lead to premature red blood cell destruction in vivo. We conclude that hemolysis with subsequent anemia in pregnant women with pyelonephritis is caused by lipopolysaccharide-induced red blood cell membrane damage. (Am J Obstet Gynecol 1991;164:587-90.)

Key words: Pyelonephritis, anemia, hemolysis

As many as 10% to 20% of women with antepartum pyelonephritis have culture-proved bacteremia, which is usually caused by *Enterobacteriaceae*.[1, 2] Whereas overt sustained hypotension is rare, other presumed endotoxin-mediated effects are more common. For example, with severe renal infection during pregnancy, endotoxemia has been implicated as the cause of transient renal dysfunction and pulmonary injury.[3, 4] In these and other studies, it was also found that anemia develops in about a fourth of women with pyelonephritis.[5, 6] Although the exact mechanism(s) by which anemia develops is unclear, it is presumed that hemolysis is caused in some way by endotoxin-mediated erythrocyte membrane injury.[7] In this investigation we characterized erythrocyte morphologic changes that are related to acute anemia in pregnant women with pyelonephritis.

Patients and methods

We studied 18 pregnant women who were admitted to Parkland Memorial Hospital for treatment of pyelonephritis. Ten of these women had attended a prenatal clinic, and the other eight had received no prenatal care. All presented with flank pain, fever, chills, nausea and vomiting, and tenderness to fist percussion at one or both costovertebral angles. Renal infection was confirmed by culture of catheterized urine and *Escherichia coli* was recovered from 13, *Klebsiella pneumoniae* from three, and *Enterobacter* organisms from two. Five of the 18 women had positive blood cultures, three for *E. coli* and two for *Enterobacter* organisms. Along with vigorous hydration, 14 women were treated with a β-lactam agent and aminoglycoside antimicrobial combined, and the other four were treated with a β-lactam agent alone. All women were given intravenous antimicrobial treatment until they were afebrile for at least 24 hours.

In addition to blood sampling as dictated by clinical care, blood was obtained for scanning electron microscopy studies. Blood for hematologic studies was also obtained from 25 women with normal pregnancy who were admitted at term in early labor.[8] None of these patients or control subjects had evidence for a chronic hemolytic process or other erythrocyte disorder, including sickle cell trait. Peripheral blood was collected into vacuum tubes that contained ethylenediaminetetraacetate and was processed within 1 hour. One milliliter of blood was centrifuged at 1000 *g* for 3 minutes. The plasma was discarded and red blood cells were suspended in a fixative solution of 1.25% glutaraldehyde in cacodylate buffer (0.1 mol/L). Three drops of freshly anticoagulated blood was added to the fixative and mixed gently. After it had settled at room temperature for 1 to 3 hours, the suspension was spun for 4 minutes at 1000 *g*, the supernatant was dis-

carded, and the cells were resuspended gently in 2 ml of 0.1 mol/L cacodylate buffer. The centrifugation-resuspension step was repeated twice, and the last suspension was refrigerated at 4° C until the cell membranes were prepared for microscopic examination.

From each subject and her control, 500 erythrocytes from contiguous fields were examined with a JEOL model JSM-35 (JEOL USA, Peabody, Mass.) scanning electron microscope. Cells were categorized according to the classification of Bessis[9] as normal discocytes or as abnormal echinocytes, schistocytes, or spherocytes. The proportion of abnormal erythrocytes was determined for each woman. Differences in the mean proportions of abnormal red blood cells among the groups of study subjects and the respective control subjects were tested by means of the Mann-Whitney test for statistical significance.[10] This nonparametric test was used because fractional values do not generally satisfy the normal assumptions that are required for parametric testing.

Results

The demographic characteristics of the 18 women with antepartum pyelonephritis were not different from those of the general obstetric population at Parkland Hospital. In 11 of the 18 women, the hematocrit decreased 5 vol/dl or more from admission to discharge (mean 4 days). In the remaining seven women, the mean decline was 3 vol/dl. Shown in Table I are the mean hematocrits that were determined in clinic, at admission, after hydration, and at discharge. In both clinic and nonclinic groups, the hematocrit decreased 4 to 5 vol/dl during hospitalization. Evidence that this was not simply due to rehydration is illustrated by the 10 women who had prenatal care. These women had taken iron supplements and had not been previously anemic. In spite of this, these women had a mean decrease in hematocrit of 8 vol/dl when determinations made during hospitalization were compared with the most recently obtained hematocrit from the clinic. Moreover, the posthydration hematocrit was decreased by a mean of 9.1 vol/dl (range 4.4 to 14 vol/dl) compared with the last prenatal hematocrit. By the time of delivery the mean hematocrit in both clinic and nonclinic women exceeded 30 vol/dl, and it was <30 vol/dl in only two nonclinic patients.

None of these women who were tested had a positive Coombs' test. Although the serum bilirubin level was not appreciably elevated (mean 0.7 mg/dl; range 0.4 to 1.7 mg/dl), urine urobilinogen was usually detected. Modest reticulocytosis in spite of severe infection provides further evidence for hemolysis. The mean reticulocyte count on admission was 1.8% (range 0.2% to 3.0%).

In Table II the mean proportions of abnormal erythrocytes from women with pyelonephritis are compared with those from normally pregnant control women. A significantly increased proportion of abnormal erythrocytes was found in women with pyelonephritis (10.3% vs 1.4%, $p < 0.001$). The most common morphologic abnormality was echinocytosis, but the proportions of schistocytes and spherocytes were also increased significantly. Representative erthrocyte abnormalities from one of these women are shown in Fig. 1.

There was no apparent correlation between the magnitude of hemolysis and abnormal red blood cell forms. By way of examples at the extremes, in one woman with 36% abnormal erythrocytes there was a 5 vol/dl fall in hematocrit; in another with 2.8% abnormal forms there was a 4 vol/dl decrease. In 15 women serial observations were performed during hospitalization to search for a trend over time. In seven women the percentage of abnormal cells decreased, in six it increased, and in two (who had 2.7% and 1.4% abnormal forms) there was no change.

Comment

Acute pyelonephritis during pregnancy causes multiple organ system derangements that apparently are mediated by bacterial endotoxin (lipopolysaccha-

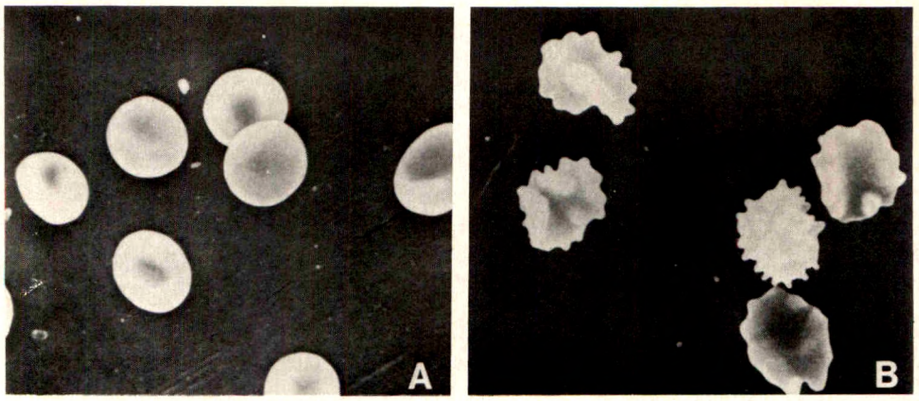

Fig. 1. A, Scanning electron microscopy of peripheral blood taken from a woman at the time of admission for acute antepartum pyelonephritis. Normal discocytes shown constituted 97% of the erythrocytes. **B,** Peripheral blood from the same woman 24 hours later and showing echinocytes that constituted 7% of erythrocytes (schistocytes were noted in 6%).

ride). These include, but are not limited to, hypothalamic, hepatic, renal, and pulmonary aberrations.[2-4] Interleukin-1 and other cytokines are released by activated macrophages and indirectly affect the hypothalamus to cause chills and fever.[11] Clinical evidence for kidney damage has been reported in nonpregnant human beings with severe sepsis,[12, 13] and Whalley et al.[3] described reversible renal dysfunction in pregnant women with pyelonephritis. Also in pregnant women with renal infection, Cunningham et al.[4] described pulmonary injury, which is characterized by adult respiratory distress syndrome in its worst form, and attributed this to endotoxemia. Thrombocytopenia commonly accompanies septicemia, and Kelton et al.[14] reported that this may be caused by endotoxin-induced platelet-associated immunoglobulin. Although poorly characterized, acute hemolysis accompanied by anemia may develop in persons with *E. coli* septicemia.[7, 15]

It was previously reported that anemia, defined by a hematocrit <30 vol/dl, develops in 25% to 30% of women who are hospitalized for antepartum pyelonephritis.[5, 6] The incidence of anemia in the current investigation was similar, and although only a third of the women had anemia, there was evidence for hemolysis in all, which was manifested by an average decrease in hematocrit of approximately 5 vol/dl. Significantly, although none of the 10 women with presumably sufficient iron who attended clinic had been anemic previously, eight had anemia that persisted at discharge. Almost all of these women with pyelonephritis had substantively increased erythrocyte morphologic abnormalities that were identified by scanning electron microscopy. Specifically, there were significantly increased numbers of echinocytes and schistocytes, and, to a lesser extent, spherocytes when red blood cells from women with renal infection were compared with those from normally pregnant women. Although we did not conduct studies to determine the longevity of these morphologic aberrations, the mean hematocrit for clinic and nonclinic patients increased

by 5 vol/dl from discharge to delivery, and only two of the 18 women were still anemic by the time of delivery.

It seems probable that hemolysis with subsequent anemia is caused by lipopolysaccharide-induced red blood cell membrane damage. It has been shown previously that a number of in vivo extraerythrocytic pertubations induce predominantly echinocytosis.[8] Similar erythrocyte membrane alterations were produced in vitro by Warren et al.[16] who described a concentration-dependent endotoxin effect on red blood cell membrane curvature. They also described a reversible discocyte-to-echinocyte transformation in erythrocytes that were treated with endotoxin. Previously, Cooper et al.[17] reported that shortened erythrocyte survival in echinocytosis resulted from "conditioning," which describes progressive membrane loss after splenic passage. Moreover, at least in bacteremic animals, endotoxin is released when antimicrobial therapy is given,[18] and we did not detect maximal erythrocyte aberrations typically for at least 24 hours after therapy was begun. Because of these findings, it seems reasonable to conclude that endotoxin-induced erythrocyte membrane changes lead to acute hemolysis and cause anemia that may accompany antepartum pyelonephritis. In this scheme red blood cells that are rendered echinocytic cannot readily traverse the splenic slits, and as membrane loss progresses, echinocytes are converted to schistocytes or spherocytes that are then rapidly destroyed.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

RFP ANNOUNCEMENT

NTD LABORATORIES, INC.

Requests for Proposals – *free Beta*™ Down Syndrome Screening

NTD Laboratories, a pioneer in prenatal genetic screening and testing, will soon request proposals to advance research and the clinical application of its work in maternal serum screening for Down syndrome and other fetal aneuploidies, particularly as that work applies to its *free Beta*™ Down syndrome screening protocol.

free Beta™ screening is distinguished by:

- Unsurpassed 80% detection rate,
- Less potential for error; No dilution of samples,
- Cost-effectiveness; Fewest Analytes, Highest detection rate.
- Low false-positive rates; Below 5%,
- Non-isotopic assays, and

Interested parties are invited to write to Dr. James N. Macri at NTD Laboratories, Inc. or Fax (516) 338-2734.

free Beta™ screening is a new Down syndrome test that detects a superior protein marker by using a recently discovered binding site on the *free Beta*™ protein. When used in combination with msAFP and maternal age, *free Beta*™ achieves a detection rate of greater than 80% in pregnancies at 14-16 weeks gestation. *free Beta*™ is a patent-pending scientific discovery by NTD Laboratories, Inc. The discovery has been reduced to practice in a superior assay system and clinical reporting protocol for investigational Down syndrome screening. The *free Beta*™ protein is unbound to the hCG molecule and is a *superior protein marker* for prenatal Down syndrome screening.

Gynecologic Oncology

An International Journal

Gynecologic Oncology has become the standard journal in this subdiscipline and is read by surgical and medical oncologists worldwide. Contributions to the journal in the field of female genital cancer encompass the clinical and basic oncologic sciences pertinent to this branch of gynecology. The journal publishes innovative papers presenting surgical procedures for cancer. The enlarged scope of the journal now encourages articles on other aspects of gynecologic surgery and reproductive medicine.

Research areas include: cell biology, cell kinetics, chemotherapy, cytology, endocrinology, epidemiology, genetics, gynecologic surgery, immunology, pathology, and radiotherapy.

The official publication of the Society of Gynecologic Oncologists; Society of Gynecologic Oncologists of Canada; Felix Rutledge Society; Western Association of Gynecologic Oncologists; The Society of Memorial Gynecologic Oncologists; New England Association of Gynecologic Oncologists; and Mid-Atlantic Gynecologic Oncologic Society

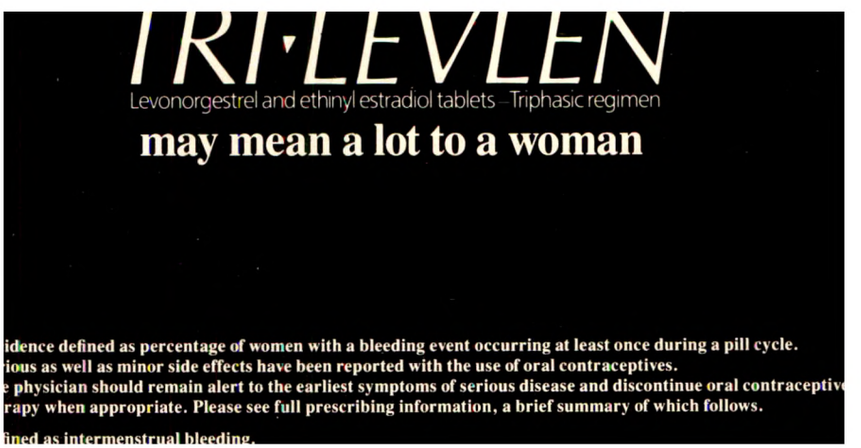
REWARDS

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gyneco-logical surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.



Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland water-ways. Centrally located, with moun-tains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

TRI-LEVLEN
Levonorgestrel and ethinyl estradiol tablets – Triphasic regimen
may mean a lot to a woman
idence defined as percentage of women with a bleeding event occurring at least once during a pill cycle.
ious as well as minor side effects have been reported with the use of oral contraceptives.
physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptiv
rapy when appropriate. Please see full prescribing information, a brief summary of which follows.
ined as intermenstrual bleeding.

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).
Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.
Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.
Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.
CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.
MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.
RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.
ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.
PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.
2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.
3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.
4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.
5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It i recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If th patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first misse period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should b apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light o these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form o contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precis information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estroge combinations to induce withdrawal bleeding should not be used as a test of pregnancy.
6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. I one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, a increased risk was apparent between 6 and 12 months of use.
7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage o patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase i triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipi metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of thes findings remains to be defined.
8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertensio may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in user and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated wit the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely t develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to norma after discontinuing the drug.
9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent o severe, requires discontinuation of OCs and evaluation of the cause.
10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. I breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. I undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule ou pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing t an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea o young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation o OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.
11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.
12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity an quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mother receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should b deferred until the infant has been weaned.
Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatmen and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 yea without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4 OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac o renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

TRI·LEVLEN®
Levonorgestrel and ethinyl estradiol tablets–
Triphasic regimen

Information for the Patient—See Patient Package Labeling
Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.
Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.
Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."
Nursing Mothers—See "Warnings."
Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.
There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.
The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses. The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.
Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.
Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.
For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Fetal panting: Yet another response to the external vibratory acoustic stimulation test

David M. Sherer, MD, Jacques S. Abramowicz, MD, Mary Lou D'Amico, RN, Tamara Allen, BS, RDMS, and James R. Woods, Jr., MD

Rochester, New York

Fetal panting at a rate of 119 respiratory movements per minute, persisting for 40 minutes after external vibratory acoustic stimulation, was noted in a fetus at 33 weeks' gestation. Subsequent fetal outcome was good. The possible underlying pathophysiologic mechanism is discussed. (AM J OBSTET GYNECOL 1991;164:591-2.)

Key words: Fetal acoustic stimulation, fetal panting

Recently, application of ultrasonographic evaluation during or immediately after fetal vibratory acoustic stimulation has been described,[1] leading to further understanding of this fetal-startle response. We describe an unusual case in which marked rapid movement of the fetal chest wall (fetal panting) was seen ultrasonographically after fetal vibratory acoustic stimulation.

Case report

A 14-year-old black patient was followed during her first gestation at the Strong Memorial Hospital Adolescent Maternity Clinic. Her pregnancy was remarkable for abruptio placentae at 28 weeks' gestation (by an early 6-week ultrasonographic examination), at which time a singleton fetus at the 10th percentile for growth with a small retroplacental hematoma was revealed. She was hospitalized and was discharged 4 days after the vaginal bleeding subsided. Nonstress tests

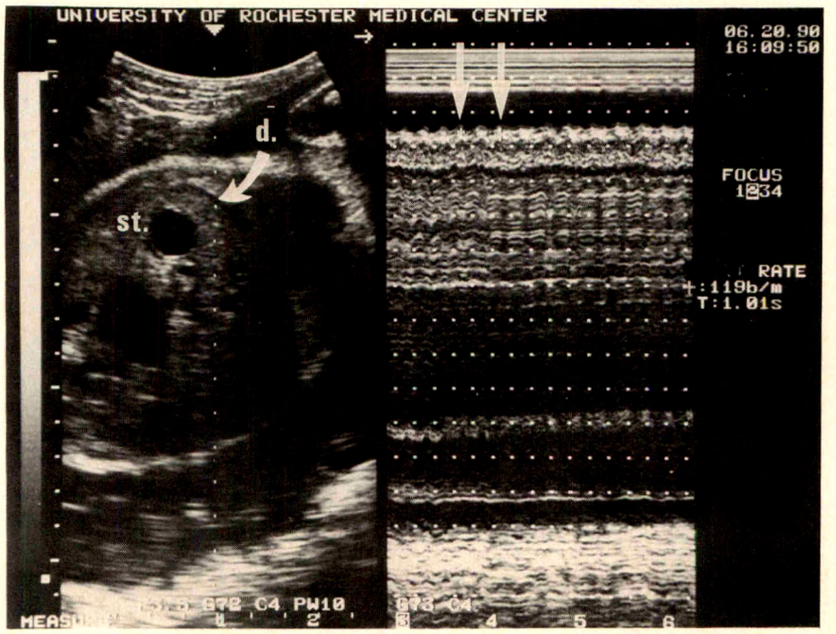

Fig. 1. Split screen ultrasonography. *Left*, M-mode cursor *(dotted line)* traversing anterior fetal chest wall and diaphragm *(d—curved arrow)*, (*st*, stomach). *Right*, M-mode shows fetal panting. *Arrows* mark anterior chest wall movement.

were performed weekly and at 33 weeks' gestation, because of a nonreactive nonstress test, fetal vibratory acoustic stimulation was performed. A reactive response was noted and a biophysical profile was obtained within minutes of the fetal vibratory acoustic stimulation. This revealed an active fetus and 10 of 10 points were given for the biophysical profile. Attention was drawn to persistent, rapid, shallow movement of the anterior fetal chest wall and diaphragm. M-mode ultrasonography with the transducer traversing the fetal diaphragm showed the rate to be 127 movements per minute. The next day, fetal vibratory acoustic stimulation was performed with continuous ultrasonographic scanning. Whereas no fetal chest movement was noted before the fetal vibratory acoustic stimulation, rapid movements of the fetal chest wall and diaphragm at a rate of 119 movements per minute were noted simultaneously after the stimulation. This continued for 40 minutes (Fig. 1). Nonstress tests were performed weekly until term. At 41 weeks' gestation, a normal male infant was delivered vaginally weighing 3330 gm with Apgar scores of 9 and 9 at one and five minutes, respectively. Umbilical artery pH was 7.35, P_{O_2} was 20 mm Hg, and P_{CO_2} was 41 mm Hg. The infant did well. Examination of the placenta did not reveal evidence of placental abruption.

Comment

Recent application of ultrasonography during fetal vibratory acoustic stimulation[1] showed an increase of fetal movements, head turning, mouth opening, tongue protrusion, cheek motion, hand-to-head movement and fetal eye blinking subsequent to such stimulation. These are all thought to represent sequelae of a startle response. In the past, fetal tachypnea has been associated with poor fetal outcome. Devoe et al.[2] reported fetal tachypnea in 18 cases during biophysical tests of 200 patients. The mean breathing rate in their study was 68.2 ± 6.4 breaths per minute. Seven of these 18 fetuses experienced perinatal morbidity. Of these, five had other biophysical abnormalities. Devoe concluded that fetal tachypnea occurs more often than previously believed and does not generally signify fetal compromise unless other biophysical abnormalities are present.

We believe the fetal panting shown in our case (at a rate of twice that noted previously[2]) may be an additional characteristic of the startle response. This case, to the best of our knowledge, represents the first reported occurrence of fetal panting as a response to fetal vibratory acoustic stimulation and, as with the majority of cases described by Devoe, was associated with a normal fetal biophysical profile and good perinatal outcome.

The increased frequency of cervical dysplasia-neoplasia in women infected with the human immunodeficiency virus is related to the degree of immunosuppression

Axel Schäfer, MD,[a] Wolfgang Friedmann, MD,[a] Martin Mielke, MD,[b] Bernhard Schwartländer, MD,[c] and Meinrad A. Koch, MD[c]

Berlin, Federal Republic of Germany

Cytologic and histologic investigations of the uterine cervix and studies of the lymphocyte functions were performed in human immunodeficiency virus–infected and human immunodeficiency virus antibody–negative women to study possible linkages between human papillomavirus–induced dysplasia and degree of human immunodeficiency virus–induced immunosuppression. Cytologic smears of the uterine cervix of 111 human immunodeficiency virus–infected women were compared with findings in 76 female intravenous drug users negative for human immunodeficiency virus antibodies and in a group of 526 women of the outpatient population of the hospital. Cervical dysplasia-neoplasia (including five cases of invasive carcinoma) was seen in 41% of the human immunodeficiency virus–infected patients. In human immunodeficiency virus–negative intravenous drug users dysplasia-neoplasia was seen in 9%, and in the sample from outpatients in 4%, including two cases of invasive carcinoma ($p < 0.01$). Cytologic features that were attributable to infection with human papillomavirus were observed in human immunodeficiency virus–infected women four times more often than in the sample from the outpatient population ($p < 0.01$). Frequency and severity of dysplasia appear to increase with diminishing numbers of $CD4^+$ helper/inducer T lymphocytes and correlated significantly ($p < 0.01$) with a loss of blastogenic response to phytohemagglutinin, pokeweed mitogen, and tetanus toxoid. These results suggest an increased risk for the development of dysplasia of the uterine cervix in women with human immunodeficiency virus infection, which is related to the degree of immunosuppression. (AM J OBSTET GYNECOL 1991;164:593-9.)

Key words: Cervical dysplasia, HIV infection, immunosuppression, human papillomavirus

The findings that some members of the group of papillomaviruses can transform cells in vitro[1] and the detection of human papillomavirus deoxyribonucleic acid in cells from cervical cancer[2, 3] suggest that human papillomavirus (HPV) may be etiologically involved in the development of cervical dysplasia-neoplasia. An association between HPV and cancer of the cervix has been suggested by epidemiologic studies.[4] A high prevalence of cervical dysplasia among women with human immunodeficiency virus (HIV) infection has been observed[5, 6] and linked to the frequent occurrence of HPV infection in HIV-positive women.[7] Although other well-established cofactors such as sexual activity, frequent genital ulcers, smoking, or use of oral contraceptives[8] must be taken into account, a direct interaction between HIV and HPV on a cellular level or in immunosuppression have been assumed to be additional cofactors.[9]

The frequent occurrence of cervical cancer and cervical intraepithelial neoplasia in immunocompromised women points to a role of immune surveillance in the development of cancer.[10] The infiltration by inflammatory cells, mononuclear cells, and T lymphocytes of HPV-induced lesions in regression is suggestive of a delayed hypersensitivity reaction.[11] An investigation of T-lymphocyte subsets in women with manifest genital HPV infection[12] showed a lower percentage of $CD4^+$ cells (helper/inducer) and a higher percentage of $CD8^+$ cells (cytotoxic/suppressor) compared with women with normal cervical cytologic evaluations. A decrease of the natural killer cell activity could be demonstrated in patients with condyloma acuminatum.[13]

During the course of HIV infection, peripheral T cells and cell-mediated immune response are increasingly diminished.[14] HIV-induced immunodeficiency has been shown to increase not only the risk for opportunistic infections but also the risk for the devel-

opment of various neoplasms including squamous rectal or oral carcinoma.[15] This poses the question of whether HIV-induced immunosuppression is an important factor in determination of the overt risk of cervical dysplasia and neoplasia in HIV-infected women. To explore these relations peripheral T cells, lymphocyte blastogenic response, and cytologic and histologic characteristics have been investigated in a cohort of HIV-infected women.

Patients and methods

One hundred eleven women, who tested positive for the HIV antibody and who were admitted to this hospital because of various gynecologic complaints or because of an HIV infection that was under regular clinical surveillance, were investigated by cervical cytologic methods. At the same time, parameters of immune functions were determined. Of the 111 HIV-infected women, 84 (76%) had a history of drug use and of sharing injection equipment. The remaining 27 women were presumably infected by sexual contact. The mean age of the patients was 28.9 years (Table I).

Intravenous drug users reported high promiscuity. Many of them had obtained drugs, or money to obtain drugs, by prostitution. Therefore it cannot be excluded that some of the intravenous drug users may have acquired HIV by sexual contact. There were no detectable differences in the frequency of cervical dysplasia-neoplasia or in the clinical or immunologic course of the HIV infection between these patients and patients who reported sexual contact as the only risk for HIV infection.

Results that were obtained in the group of HIV-infected women were compared with findings in a group of 76 women who were addicted to drugs and whose test results were seronegative for HIV. The mean age of this group was 26.8 years. The extent of reported promiscuity and smoking (Table I) was comparable in both groups. Amenorrhea that was caused by opiate use and indolence about possible pregnancies explains the fact that hormonal contraceptives are rarely used by these women.

Results of cervical smears from 526 women who were seen in our outpatient clinic served as controls (mean age, 27.2 years). The vast majority of the women who visited our outpatient clinic did not have regular preventive gynecologic checkups. Minor gynecologic complaints such as itching, vaginal discharge, or lower abdominal pain were the leading causes for consulting the clinic. Because of the location of the hospital, these women represent a population of lower socioeconomic status.

Papanicolaou smears were used for cytologic studies of the uterine cervix. The results were classified as follows: 1 = normal (without signs of dysplasia), 2 = dysplasia (comprising all degrees of dysplasia), and 3 = invasive carcinoma. Cytologic criteria for HPV-induced alterations were the identification of koilocytes and dyskaryocytes in these smears.[16] The investigation was completed by colposcopy. In all patients with colposcopic findings that were suspicious for cervical intraepithelial neoplasia or a cytologic diagnosis of persistent slight or moderate and severe dysplasia, a histologic confirmation by biopsy was obtained.

HIV-induced disease was classified into four groups as proposed by the Centers for Disease Control.[17] This classification relies on clinical findings of HIV-related symptoms. In short, group I included women with acute HIV infection, and group II comprises all HIV-infected women without clinical symptoms. Patients with lymphadenopathy are classified into group III and patients with conditions that were related to acquired immunodeficiency syndrome and acquired immunodeficiency syndrome were assigned to group IV. Groups II and III are subdivided depending on absence or presence of abnormal immunologic findings.

Immunologic studies. Heparinized venous blood was collected for leukocyte counts and functional lymphocyte tests. Lymphocyte subpopulation was determined by flow cytometry with fluorescence-labeled monoclonal antibodies (Coulter) against $CD2^+$ (T lymphocytes), $CD4^+$, and $CD8^+$.

A high individual variability was observed in these tests. To compensate for this variability, mean values were calculated from at least three tests that were performed during an observation period of 6 to 12 months. On the basis of these data, patients were classified into four groups (T1 to T4), which represent increasing stages of $CD4^+$ cell depletion. They were distinguished as follows: T1—no detectable changes in the number of $CD2^+$ lymphocytes, $CD4^+/CD8^+$ ratio >1; T2—$CD4^+/CD8^+$ ratio <1, $CD4^+$ cell counts >400/μl; T3—$CD4^+$ cell counts between 400 and 250/μl; T4—$CD4^+$ cell counts <250/μl.

Table II. Correlation of cytologic signs of HPV* to dysplasia/neoplasia

	No signs of dysplasia	*Dysplasia-neoplasia*	*Total*
Outpatients	54/505 (11%)	7/21 (33%)	61/526 (12%)
HIV-negative IDUs	11/69 (16%)	4/7 (57%)	15/76 (20%)
HIV-positive	17/65 (26%)	36/46 (78%)	53/111 (48%)

IDUs, Intravenous drug users.
*Koilocytes or dyskaryocytes.

Lymphocyte functions were determined with a whole-blood lymphoproliferation assay as described previously.[18] In short, heparinized venous blood was diluted 1:8 in the *synthetic culture medium* RPMI 1640 (Biochrom), which was supplemented with penicillin, streptomycin, and glutamine. Subsequently 100 μl of this suspension was added to 100 μl dilutions of phytohemagglutinin (20, 10, and 5 μg/ml), pokeweed mitogen (20, 10, and 5 μg/ml), and tetanus toxoid (10 and 5 μg/ml) in U-bottom microtiter plates. Cultures were incubated for 5 days. Proliferative responses were determined by measuring the amount of incorporated tritiated thymidine after labeling for 5 hours. For each mitogen or antigen concentration, determinations were made in triplicate. Results from 240 healthy women served to determine baseline values. As an indication of an impaired proliferative response, only significantly decreased values of tritium incorporation below the 5th percentile of the healthy controls were considered. Titers of antitetanus antibodies were determined with an enzyme immunosorbent assay (detection limit: 0.15 units of antitoxin per milliliter).

On the basis of the data that were obtained, patients were classified into five groups (M1 to M5), which represent increasing stages of deficiencies in the lymphoproliferative response. This classification was developed on the basis of long-term observations of more than 200 HIV-infected individuals (unpublished observations). The different stages are characterized by: M1—normal blastogenic response to phytohemagglutinin, pokeweed mitogen, and tetanus toxoid, ≥0.3 U/ml of antitetanus toxoid antibodies in the serum; M2—decrease of lymphocyte responsiveness to tetanus toxoid only; M3—as M2 and decrease of lymphocyte responsiveness to pokeweed mitogen; M4—as M3 and decreased titers of circulating antibodies against tetanus toxoid <0.3 U/ml; and M5—as M4 and decrease of phytohemagglutinin-induced lymphocyte transformation.

Results

Cytologic evaluation of the uterine cervix in the investigated collectives. Between August 1985 and February 1989, 111 HIV-infected women were investigated. The shortest period of observation was 6 months. The clinical investigation included a stage determination of HIV disease, cytologic examination of the uterine cervix, histologic examination when indicated, and investigations of the immune functions.

Of these patients 46 (41%) had cytologic smears that were suspicious for cervical dysplasia/neoplasia including five cases of invasive carcinoma (Table I). A consistently normal cytologic evaluation during the time of observation was found in 65 (59%) of the 111 HIV-infected women. In 12 cases progression of dysplasia and in 11 cases spontaneous regression of dysplasia could be observed.

Of the 76 HIV-negative women who were addicted to drugs 69 (91%) exhibited a normal cytologic evaluation, and only seven (9%) had dysplasia. Invasive carcinoma was not seen in this group. The screening results for abnormal cytologic smears of the uterine cervix in women who visited our outpatient service are included in Table I. Normal cytologic smears were obtained from 505 (96%) of 526 women, and 21 (4%) showed varying degrees of dysplasia/neoplasia including two cases with histologically confirmed invasive carcinoma.

Dysplasia was seen in the group of HIV-infected women about four times more often than in the group of intravenous drug users without HIV infection ($p < 0.01$) and about 10 times more often than in the outpatient population ($p < 0.01$).

In the group of HIV-negative female intravenous drug users dysplasia was twice as frequent as in the outpatient population ($p = 0.02$). Signs for HPV infection (koilocytes and dyskaryocytes) were seen significantly more often in HIV-infected women (Table II).

Colposcopy and histologic diagnosis in HIV-infected women. By colposcopy 83% (38/46) of the HIV-infected patients with dysplasia were conspicious for cervical intraepithelial neoplasia. Thirty-two percent (14/46) had additional alterations that were attributed to HPV, such as condylomas. Biopsy specimens of uterine cervix were obtained from 38 HIV-infected women. In addition to the histologic confirmation of five invasive carcinomas, cervical intraepithelial neoplasia III was seen in 13 cases, cervical intraepithelial

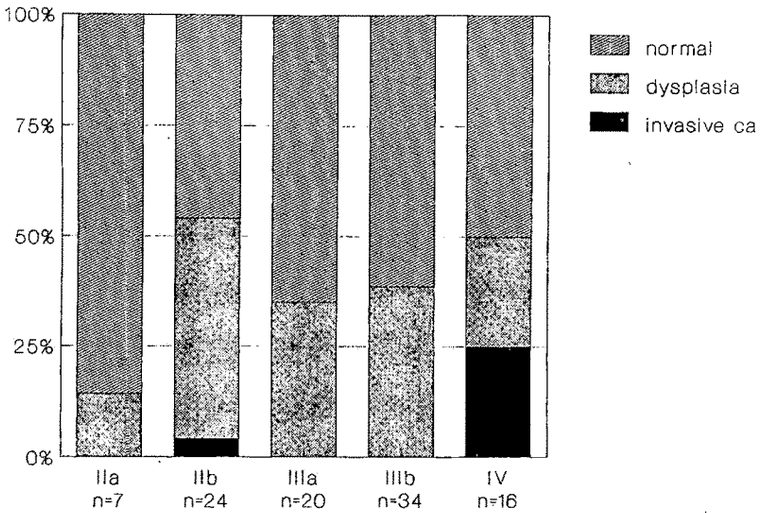

Fig. 1. Centers for Disease Control classification of HIV disease and cervical dysplasia.

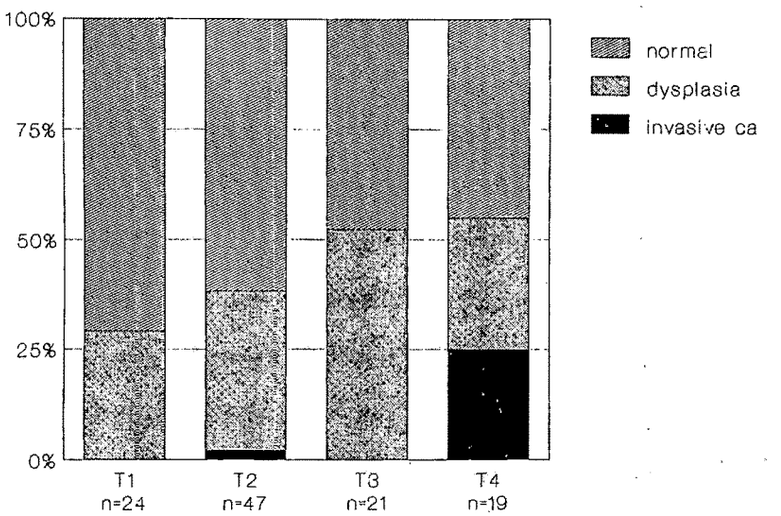

Fig. 2. Cervical dysplasia and neoplasia in correlation to $CD4^+$ lymphocyte depletion in HIV-infected women.

neoplasia II in 11 cases, cervical intraepithelial neoplasia I in 7 cases, and cervicitis in 2 cases. Depending on the histologic severity of cervical intraepithelial neoplasia, 21 women underwent conization. One hysterectomy and three Wertheim-Meigs operations had to be performed. The International Federation of Gynecology and Obstetrics staging of the carcinomas was in two cases stage IA, in one case stage IIA, in one case stage IIB, and in one case stage III with an additional vulvar carcinoma.
